Coastal Changes, Gradual

B. G. Thom¹ and P. J. Cowell²

¹Faculty of Built Environment, University of New South Wales, Sydney, NSW, Australia

²Coastal Studies Unit Department of Geography, University of Sydney, Sydney, NSW, Australia

The concept of gradual coastal change can be seen as embracing different contexts, both spatial and temporal. It is conceivable that gradual change may include those depositional and erosional events that have taken millions of years to produce present-day coastal landforms at one end of the spectrum, while at the other end slow and imperceptible accretion to beaches after storms may represent another form of gradual change. Therefore, a wide-ranging time frame may be used covering geological, engineering, and arguably event scales as depicted in Fig. 1.

This figure demonstrates how high frequency, low magnitude processes at shorter time scales can be superimposed on longer-term oscillations and trends at scales of millennia and longer term as reflected in depositional and erosional land forms.

Cenozoic Geologic Scale

Coastal geomorphologists have a long-standing interest in the evolution of coastal landforms from Tertiary to Quaternary

Coastal Changes, Gradual, Fig. 1 Spatial and temporal scales of coastal geomorphic change depicting examples of features formed at different scales and how oscillations in magnitude and frequency of

processes may be superimposed on longer-term trends (e.g., progradation of a strandplain with beach cut and fill cycles superimposed as at Moruya, New South Wales, Australia, see Thom and Bowman 1981)

times. Many coastal regions show an historical imprint or inheritance of depositional or erosional processes reflecting changes in shoreline position as sediments accumulate or cliffs erode. In glaciated areas, the impact of gradual coastal accretion or erosion from Tertiary times is rarely apparent. Similarly, where tectonic and volcanic activities prevail there is little evidence of shoreline features of pre-Quaternary age. However, tectonic uplift as seen, for instance, along the Huon Peninsula in Papua New Guinea, can provide a mechanism for preserving the remnants of gradual coral reef accumulation over hundreds of thousands of years which correlate very well with glacial to interglacial climatic and eustatic cycles (Chappell and Shackleton 1986).

Classic thinking in coastal geomorphology, epitomized by the work of Douglas Johnson (1919), dramatically demonstrated the nature of gradual change following the application to coasts of the Davisian cyclic model in geomorphology. Assumptions built into this model may be queried, but the basic notion of change driven by the interaction of marine

forces (especially waves) and the land still underpins any conceptual framework for understanding how coasts evolve over time. The importance of sea-level change during the Quaternary is now seen as a major factor in coastal geomorphology, a phenomenon of relatively limited significance in the Davis/Johnson model. Shepard, Russell, Fairbridge, Armstrong Price, Steers, and Guilcher (and others) are of a generation that assessed coastal landforms in different regions of the world from a Quaternary perspective. They showed how erosional, and especially depositional landforms, over time, have changed their character under different sea-level conditions. Many coastal regions experienced post-depositional modification and transformation after primary wave, tidal and wind processes have performed their work (Thom 1975).

The Australian coast contains many examples of gradual change in coastal environments during the Cenozoic. These features have formed since dislocating tectonic forces that ripped the continent apart from Gondwana remnants

essentially stopped operating about 60 million years ago. On the east coast, the narrow continental shelf has been subjected to very slow marginal subsidence. This has facilitated two geomorphic outcomes: shelf-edge accretion of a sediment wedge ca. 500 m in thickness, and an inner-shelf abrasion surface up to 10 km wide and ca. 1,000 km long (the East Australian Marine Abrasion Surface – EAMAS). The surface is now veneered with late Quaternary sediments and is entrenched by infilled paleo-valleys carved by rivers draining to lower sea levels. The surface culminates on the landward side with discontinuous marine cliffs cut into Mesozoic or Paleozoic rocks often over 100 m in height and representing truncated spurs and ridges of drowned valleys and plateaux (as seen around Sydney). We are uncertain of the precise age of initiation of the surface and cliffs, but it is easiest to conceive of these features as time-transgressive evolving progressively over millions of years during periods of relatively higher sea level.

Another large-scale Australian example that reflects gradual accumulation of sediments are the barrier-lagoonal deposits formed over millions of years within the lower Murray-Darling basin. In this region, relative sea level since the early Tertiary has fallen. Sands, including heavy minerals such as ilmenite, form horizontally stacked barriers which in Quaternary times have been partially reworked into terrestrial dune fields. Similar “stepped” or extensive strand plains initiated in the Tertiary and extending through the Pleistocene into the Holocene have formed in southwest Western Australia near Perth, in parts of southeast Brazil, and along the Atlantic coastal plain of the United States.

Holocene Geologic Scale

At the other end of the geologic scale are coastal phenomena which are the result of processes operating at or close to present sea level over the last 6,000 years or so. Within this time frame, erosion and/or deposition can initiate and reconstitute sand barriers, tidal flats, river mouths, tidal deltas, coastal dunes, and rock platforms at the macro scale, and a myriad of landforms at a micro scale. Use of techniques of drilling and dating have enabled age structures and sedimentary histories to be reconstructed from Holocene deposits in coastal areas of many parts of the world.

In areas of postglacial rebound beach deposits dated 6,000 years BP may occur 100–150 m above present sea level (e.g., Gulf of St Lawrence), whereas for areas marginal to the great deltas, like the Mississippi, deposits of similar age may have gradually subsided below sea level and be buried by younger sediments (see Carter and Woodroffe 1994). In contrast, those coasts experiencing a much more passive neotectonic regime, such as eastern Australia, witness beach/

foredune ridge accumulation at about present sea level not only in the Holocene, but also in the last and penultimate interglacials (Roy et al. 1994; see Hopley 1994, for a review of gradual coral reef accumulations in similar tectonic settings).

One conclusion which can be drawn from an analysis of Holocene sand barriers is how gradual processes of accretion are periodically interrupted by erosion or reduced rates of accretion. The result is a strand plain with distinct linear ridges (beach or foredune) parallel or sub-parallel to the present shoreline. Changes in sediment budgets are critical in the gradual evolution of strand plains. As pointed out by Cowell et al. (1999) sand may be supplied from the shoreface as well as littoral sources in order for accretionary processes to work. Closed sediment compartments highlight the effectiveness of gradual onshore transport of sediment from the lower shoreface in certain areas (see Fig. 2; Roy et al. 1994). These areas are in contrast to those “leaky” compartments dominated by littoral sand transport associated with river mouth (inlet) or headland bypassing.

Engineering Scale

Even closer to the present are those features which result from erosion or deposition over periods of 2 years or more. Increasingly, coastal geomorphologists are recognizing the impact of oscillations in climatic conditions leading to changes in beach volume, beach alignment, inlet openings/closures, river-mouth bar migration, dune vegetation recovery, etc. However, some of these changes may reflect “self-organization” of morphodynamic conditions involving positive and negative feedback effects independent of climatic forces (see Cowell and Thom 1994, citing field studies in the United States, Netherlands, and Australia)

Recovery of the subaerial beachface in width and thickness following a period of sudden storm wave erosion is well documented in coastal literature (Komar 1998). Storm impacts in winter followed by gradual summer accretion are characteristic of many coasts in North America (e.g., California) and Europe. The severity of impact may be enhanced during El Niño years as in Oregon, and that gradual beach recovery may take longer after such severe winter events (see Komar 1998 for description of El Niño storm impacts). Contrasting situations occur in the southwestern Pacific where beaches may accrete through many years (winter and summer) influenced by El Niño only to erode drastically in La Niña or storm-dominated periods (Thom and Hall 1991). The role of the Pacific Decadal Oscillation (PDO) as a factor in driving beach cycles of erosion and accretion is now seen as a significant phenomenon which may explain the

Coastal Changes, Gradual, Fig. 2 Simulated strandplain development during the Holocene at Tuncurry, New South Wales, Australia (after Cowell et al. 1999). The simulation involved a constant sea level for 6,000 years and an across-shore sand supply from lower to upper

shoreface averaging 1.1 m^3 per meter of shoreline together with a steady increase in depth of the lower shoreface at a rate of 0.002 m/year decreasing linearly with distance to 10 km seawards of the present coastline forming 80% of sand now in the strandplain.

timing of events that do not easily fit ENSO patterns. El Niño and La Niña can be seen as phenomena lying on top of the large-scale temperature and sea-level height distributions determined by the PDO.

Understanding processes of gradual beach accretion is of significance in beach management. Monitoring beach change by photogrammetric and/or field survey methods yields valuable information on how quickly all or part of a beach may recover following a stormy period. Beaches and foredunes in New South Wales took 5–10 years to reach pre-storm positions following the last major episode of erosion in 1974 (Thom and Hall 1991). During phases of “gradual and imperceptible” accretion, landowners with land title tied to an “ambulatory” boundary (such as mean high water mark) may seek a redetermination of their land title to claim accreted land. Under the English “doctrine of accretion” exported to many other countries, the boundary remains fixed if sudden erosion cuts back into this new land. A consequence is for landowners to seek to defend their properties with seawalls and bulkheads against erosion. Beach amenity can suffer as a result of these actions (Titus 1998).

Gradual change in coastline position and form, in tidal flat morphology, in the nature of inlet openings, and in the vegetative cover of coastal dunes are phenomena that affect the lives of millions of people. Understanding the dynamics of gradual changes in coastal geomorphology requires monitoring and historical reconstruction using a variety of techniques and analytical procedures. The use of simulated modeling, as seen for instance with the Shoreface Translation Model developed by Cowell et al. (1995), highlight a way of achieving such an understanding when coupled with a knowledge of geomorphic history and processes (see Fig. 2).

Coastal Changes, Rapid

David B. Scott
Department of Earth Sciences, Dalhousie University,
Halifax, NS, Canada

Introduction

There are many definitions of what might be called rapid events occurring on coastlines from sea-level movements caused by global warming and/or cooling (10s to 1000s of years) to tsunamis that occur in seconds. In this entry the types of rapid changes discussed will be of the more instantaneous nature from *tsunamis* (*q.v.*) to *storm surges* (*q.v.*), the type of damage done and what the events leave as a trace in the geologic record. These phenomena were deemed sufficiently important by UNESCO/IGCP (International Geological Correlation Program) to form an IGCP project (IGCP 367) that lasted for 5 years (1994–98), where over 500 people from 70 countries were involved working on almost every aspect of rapid change in the coastal zone. Much of this entry will be drawn from the five volumes produced from that project (Scott and Ortlieb 1996; Shennan and Gehrels 1996; Murray-Wallace and Scott 1999; Scott 1999; Stathis et al. 2000).

Climatic Events

Storms

By far, the most dramatic of climatic events are hurricanes or typhoons as they are called in the Pacific. These events produce profound changes on coastlines and particularly man-made structures in the coastal zone. The effects are of two types, wind damage and water damage from elevated tides and torrential rains causing coastal flooding. At the center of a hurricane winds can reach over 200 km/h and storm tides can be as much as 8 m above normal. The amplitude of the storm tide depends on the barometric pressure (the lower the pressure, the higher the tide), the wind speed which

causes the water to pile up onshore and the natural state of the tide (i.e., high versus low tide stage). The worst scenario for high storm tides is low pressure and high winds coinciding with a normal high spring tide.

The type of damage done by wind consists of knocking down of forests as occurred in hurricane *Hugo* in South Carolina (USA) in September of 1989 when the eyewall swept through a national forest and simultaneously knocked down most of the forest in a few seconds. Together with that it also destroyed many coastal man-made structures. Probably the most damage and deaths were caused by the storm surge, which at the eyewall location was 6 m above normal. However, even 50 km from the direct hit, the storm surge was almost 3 m. A purely human problem was sorting out which phenomenon caused the damage, the wind or the water, because many people did not have government flood insurance, which meant that their losses were not covered by their commercial hurricane insurance.

Maybe not too surprisingly the traces left in the naturally occurring geologic record are much less profound. At the eyewall hit of *Hugo*, there was a 10 cm sand layer but at a location 50 km north there was no sedimentological trace and in the extensive marsh areas there was not even a thin sand layer (Collins et al. 1999), the natural systems can act as a buffer to storm events, perhaps a lesson to the human population. The hurricanes do leave a trace in nontidal *coastal inlets* (*q.v.*) of either small sand layers or reworked microfossils, which can be used to build a chronology of storms on some coastlines (Liu and Fearn 1993; Collins et al. 1999). Also strong surges and sustained winds (either from hurricanes or long lasting winter storms such as “nor’easters” on the Atlantic coast of North America) can create washovers and change inlet positions in *barrier island* (*q.v.*) systems.

Global Warming

This effect causes a general sea-level rise on scales from 10s of years to 1000s of years both by melting of glacial ice caps and steric expansion of the ocean, which may amount to 30–40 cm. Depending on the coastal gradient this may or may not be significant.

It is difficult to measure these changes (Pirazzoli 1991) because they are usually on the order of a few centimeters. Mostly they have been detected by *tidal gauges* (*q.v.*) for the last 50 years (Pirazzoli 1991) but these measurements are sometimes questionable. Some *biological markers* are now capable of measuring very small changes (± 5 cm) in sediment records (Scott and Medioli 1986) such that it is possible to measure rapid sea-level changes in the late Holocene (e.g., Scott and Ortlieb 1996). It is these mid-Holocene measurements that may help us to understand the suggested *sea-level rise* (*q.v.*) to be caused by anthropogenic *global warming* (*q.v.*).

Seismic Events

Earthquakes

Sudden land movements on coastlines can either instantly emerge or submerge coastlines and any structure that might be in the way. This is particularly a problem around earthquake prone coasts such as the Pacific Rim and most of the northeastern Mediterranean.

The type of records preserved are often in coastal marshes because they remain depositional and their strong vertical zonations help to show sharp vertical surface changes, that is, sudden change from forest to marsh if the land drops or vice versa if the land emerges (Atwater 1987; Atwater et al. 1995; Shennan et al. 1999). There are outstanding records of these phenomena all up and down the west coasts of both North and South America. In rocky coastline areas, *biological markers* maybe uplifted far above their natural range, providing a good indication of rapid change and the magnitude of that change (Ortlieb et al. 1996).

Extended records of these events have been documented in the northwestern part of the United States and southern British Columbia, Canada that show a 300–500 year periodicity for magnitude 8 or 9 (on the Richter Scale) earthquakes (Atwater 1987) over the last several thousand years. Until recently, it was difficult to plan based on a 300-year return time but Shennan et al. (1998, 1999) found in two separate places that there appeared to be a precursor event between one and three years prior to these events that could be detected in coastal forest sequences that submerged during a major seismic disruption. The most compelling evidence is from the traces left by the Great Alaska Earthquake of 1964 that was the second largest seismic event ever recorded at 9.2 on the Richter Scale. The evidence from this quake is convincing because unlike the prehistoric quakes in Oregon (Shennan et al. 1998), in Alaska, we know exactly when the event occurred and we know absolutely that the forest layer was above tidal influence before the March 26, 1964 quake. What is seen is a small change in both diatom and foraminiferal assemblages in the forest *before* the quake that indicate a slight subsidence, maybe 30 cm, that was not detected by anyone living there or by macro-vegetation (Scott et al. 1998; Shennan et al. 1999). So it is possible that there may be a technique now that we can use as an early warning system for these mega-quakes.

Tsunamis

Tsunamis (q.v.) are perhaps the most spectacular and frightening of the coastal effects caused by earthquakes. They are large wavelength, fast moving waves resulting from the rapid land slumps or uplifts caused by earthquakes in offshore areas. When they are in the deep water of the open ocean they are hardly noticeable but when they reach the shallow coastal regions the energy is converted to wave

height, which in many cases can reach as high as 20 m. The most recently documented cases at this writing were the 1994 Java (Dawson et al. 1996) and the 1998 Papua New Guinea tsunamis where several thousand people were killed (McSaveney et al. 2000).

Tsunamis also leave highly detectable traces in coastal deposits in the form of sand layers contained in marsh or nontidal *coastal pond* sediments. However, these traces cannot be reliably separated from hurricane layers, so if both phenomena occur in the same area it could be confusing to sort out which is which. As with storm traces, the best evidence for offshore transport is the presence of marine microfossils. Many times the tsunami will leave no trace if it travels over hard substrates.

The occurrence of tsunamis is limited largely to the Pacific Rim where they can occur either very close or very far from the actual seismic event; an example of a distant catastrophic tsunami was the killing of several people and destruction caused by a tsunami in Crescent City, California (USA) resulting from the 1964 Alaska earthquake whose epicenter was several thousand kilometers to the north.

Sedimentation/Erosion Events

Natural Changes

There are rapid events in coastal areas caused simply by rapid sediment events that may be a result of flood deposits, rapid deforestation caused by forest fires, or any type of event that changes the sediment budget in a dramatic sense to cause a shift in morphology of the coastline. In the case of a forest fire, large amounts of erosion as a result of deforestation would place sediment into *coastal inlets (q.v.)* causing rapid infilling or conversely, if a sediment source is reduced it can cause the shoreline to retreat rapidly in the absence of any other effects (e.g., sea level or storms).

Anthropogenic Causes

By far the most spectacular rapid sedimentation events are caused by human intervention. They are almost too numerous to mention but almost every marine *delta (q.v.)* in the world is being influenced by sediment starvation which causes rapid land loss as the delta continues to subside with no replenishment of sediment (e.g., the Nile and Mississippi Deltas). The starvation results from dams either that trap the sediment upstream (the Nile) or diversions of the rivers, which do not allow the river to switch back and forth (the Mississippi).

Other less spectacular but damaging rapid sedimentation events are caused by careless placement of structures on the coast that impede *sediment transport (q.v.)* rapidly changing the balance of erosion/ sedimentation.

Summary

Rapid coastal changes can take many forms; only a few of the most obvious examples are discussed here. Often the geologic record of these events is difficult to detect, especially in dynamic coastal environments, where tidal activity reworks most of the record. The records are best in nontidal *coastal ponds and inlets* where an extreme event brings in allochthonous sediment that is then sandwiched in quiet water, often organic deposits and are relatively simple to detect and date.

Coastal Climate

David Greenland

Department of Geography, Louisiana State University,
Baton Rouge, LA, USA

Three factors are important in an explanation of coastal climate. The first is the juxtaposition of two surfaces, land (or in some cases, ice) and water, of very different properties. The second is the geographic location of the coast with respect to continental masses and global-scale atmospheric and oceanic currents of air and water, respectively. The third is the topography of the coast and its hinterland. We must also take into account temporal and spatial scale issues so as to order the different aspects and to maximize our understanding of coastal climates. Scale will be used as an organizing framework in the following account.

Several useful data and information sources exist for an entrance into the topic of Coastal Climatology. One is an encyclopedia entry under the same topic name by Walker et al. (1987) in *The Encyclopedia of Climatology*. A second is the Master Environmental Library that is an online data source for environmental data for coastal modeling applications (Allard and Siquig 1998).

Time and Space Scales

Climatologists recognize different types of climate according to their time and space scales. The local wind currents that redistribute sand around a beach sand dune and the different

temperatures on the sunny and shaded side of a stand of beach grass would be in the realm of *microclimatology*. Different climates formed by the different surfaces and local climatic interactions as one might traverse the sand of a barrier island, the water of its related lagoon, the inland coastal marshes, and the forest or agricultural land of the immediate hinterland would constitute a study of *topoclimatology*. A sea breeze might penetrate inland some 75 km from the shore on a given day and would represent a phenomenon studied in *mesoclimatology*. Climatic variable value gradients parallel to the coastline are usually much steeper than those that are perpendicular to the coastline. The geography of the US Pacific Northwest (PNW), for example, gives rise to well-marked gradients in values of climatic variables both in the latitudinal (north-south) direction but also in the longitudinal (west-east) direction. This is not uncommon for coastlines that have some north-south alignment. The location of a coast in relation to global latitude, continental geography, hemispheric-scale winds and storm tracks in the atmosphere, and surface water currents in the ocean, and the state of teleconnective indices such as the Southern Oscillation and North Atlantic Oscillation, would help explain its *macroscale climatology*. The passage from micro to macroscale defines a scale hierarchy. Most scale hierarchies in Earth Sciences, including coastal climates, have at least three characteristics. First, events on the larger scales tend to set the context for those on the scale below. Second, explanation of events on one scale is best given by reference to events on the scale immediately above and below the scale and phenomenon in question. Third, at least at the lower end of the hierarchy, there tends to be a direct relationship between time and space scales. For example, ephemeral events, like an eddy in the wind, happen on small time and space scales while some other events, like a hurricane, sometimes take many days to run their course and have the potential to affect a relatively large geographic area.

Microscale Coastal Climates

Wind is the principal climatic variable at the microscale in coastal climates and its interaction with topographic and biologic factors has long been studied. Three factors are important at this scale. First, wind at coastlines tends to come from a predominant direction often from offshore. This has the effects of distributing sand and sand dunes in particular ways, and of sometimes shaping the vegetation canopies. The actual type of sand dune formed has been suggested to be a function of the supply of sand, the density of vegetative cover, and the average wind speed (Strahler and Strahler 1992, p. 406). Second, the capacity of wind to carry sand is an exponential function of its velocity. Thus when wind speeds are decreased, by, for example, the presence of vegetation or a fence on a beach, then sand

and other particles being transported are rapidly deposited. Vegetation and wind thus have a synergistic interaction in stabilizing sand movement. Third, typically wind velocity increases logarithmically with height. This fact needs to be taken into account when designing high-rise buildings in coastal environments. Pilkey et al. (1998, p. 254) have noted that at any given height pressure from the wind is greater near the shore than it is inland.

Topoclimatology

The coast, interpreted broadly, may be formed of many different surfaces including water, sand, soil, rock, and a variety of vegetated and urban surfaces. Each one of these surfaces has a different energy and moisture balance, and depending on its roughness, a different degree of momentum transfer with the atmosphere. These differences might not be too important on the topoclimate scale on a coastline with a steep cliff topped with relatively homogeneous vegetation because the climatic differences would be overwhelmed by both smaller- and largerscale processes. However, the differences are important on a coastline typified by a barrier island, lagoon, and hinterland series on days when the large-scale wind is not too strong. The differences are important because they will form a set of distinctly different microclimates that will relate, at least, to the flora and fauna of the area.

Salt transport by wind is also important at this scale. The concentration of salt particles near the surface in coastal climates is directly related to the wind speed (Bigg 1996). A high number of salt particles makes the coastal air very hazy. The salt particles attract water vapor and play an important role in raindrop formation. Damaging salt spray can sometimes have a pruning effect on coastal vegetation. How far inland or how high up a cliff this effect can occur is determined by wind flow and its interaction with topography on the scale in question. Soils near coasts are typically high in salts transported by wind from the ocean.

Mesoclimatology: The Land–Sea Breeze Circulation

It is the different properties of the water and land surface that ultimately lead to the land-sea breeze phenomenon – one of the most studied features of all aspects of coastal climates. The circulation is developed at mid and low latitude coasts on days when larger-scale wind systems are not predominant. Anticyclonic weather in summer time provides an ideal context. The circulation is found both on maritime and freshwater coasts. At the surface of the Earth, the land-sea breeze circulation takes the form of winds coming from water surface during the day and from the land during the night. The surface

of a water body usually manifests only a small daily range of temperature. Oke (1987) has outlined the four reasons for this. Solar radiation can easily penetrate a water surface and thus heats a deep layer and not just the surface itself. Convection currents and mass transport in the water permits any heat gain or loss to be spread throughout a large volume of water. Evaporation from the water surface cools the water surface and helps promote vertical mixing within the water itself. Water has a high thermal capacity compared with soil and thus takes about three times the amount of heat to raise its temperature by 1 °C as for the same volume of soil. Thus there is a reduced flow of sensible heat from the water surface to the air compared with that over the land during the day. This leads to a reduced warming rate of the air over the water compared with that over the land surface. As described by Oke (1987), greater sensible heat flow over the land in the morning heats the air columns more rapidly and to greater heights than over the water. The atmospheric pressure well above the surface of the land is higher than at the same level over the water. The resulting horizontal pressure gradient results in airflow at upper levels toward and out over the water surface. This flow ultimately produces a higher atmospheric pressure at the surface over the water that, in turn, forms a cross-coastline flow of air from the water to the land. This surface level flow is known as the *sea* or *lake breeze*. The *land breeze* starts in the evening because of the greater contraction and cooling of the air columns over the land compared with the sea.

Oke reports that the daytime sea breeze circulation has greater vertical and horizontal extents and larger wind speeds than the land breeze because it is driven by solar forcing. Typically, the sea breeze might have a velocity of 2–5 m/s, a depth of 1–2 km, and extend inland as far as 30 km. The land breeze characteristically has a velocity of 1–2 m/s and a smaller extent than the sea breeze. If the sea breeze is forming in a location where there is cold upwelling water, then the air formed over this water may be cool enough to continue the sea breeze circulation all through the night and not have a land breeze develop at all.

The sea breeze brings with it air that is cooler and more humid than the air found over the land. This cool air plows underneath the warmer air over the land and forms a localized cold front known as a *sea breeze front*. The sea breeze front gradually advances inland during the day and is associated with the development of sea breeze cumulus clouds. These clouds are often taken by the counter (seawards) flow above the surface and dissipate because they are decoupled from their moisture source. Purdom (1976) showed that some parts of the front displayed higher concentrations of convection than in others. He found that the shape of the coastline in some places created stronger upward vertical velocities. Kingsmill (1995) documented for summer months the collision of a sea breeze front traveling from the east side of the Florida peninsula with a gust front traveling from the west.

Interestingly, he found that convective activity was most prominent just prior to the collision of the two fronts rather than at the time when the two collided. Oke (1987) has suggested that if the sea breeze travels far enough inland then the influence of the Coriolis force will affect its direction and the breeze will end up traveling parallel to the coast. A fairly deep penetration of the sea breeze front inland was observed in April 1999 at Wokingham, which is 75 km inland from the southern coast of England. The passage of the front was accompanied by an increase of the dew point temperature of 4 °C and a change of wind direction from 70° to 210° (Burton 2000).

The climatology of sea (lake) and land breezes is highly variable depending on the particular location being considered. A 15-year study of Lake Michigan found that lake breezes tend to occur more frequently along the eastern shore of Lake Michigan than along the western shore (Laird and Kristovich 1998). In addition, there was a gradual increase in the number of lake breeze events from May through August, then a slight decrease into September. The distribution of the frequency of land breezes is similar to that of the lake breezes from May through September, however, they occur about 10% less often than the daytime lake breeze circulation. Typically, sea breeze activity is observed on the south coast of England on 75 days during the year (Burton 2000).

The land-sea breeze circulation has many practical implications. Oke (1987) quotes one study in which tobacco leaves near the coastline of Lake Erie were damaged by ozone that had been formed over the lake from lakeshore city pollutants and then transported back over the shore and tobacco crop by the lake breeze. In another study, quoted by the same source, blister rust disease impacted pine trees 15–20 km from the Lake Superior lakeshore. This impact was thought to be due to spores from bushes located between the diseased trees and the lake and transported out over the lake at night, back aloft by the counter airflow of the land breeze, and then descending upon the pine trees. Michael et al. (1998) showed that during spring and summer, sea breeze circulations can strongly influence airport operations, air-quality, energy utilization, marine activities, and infrastructure in the New York city region. Here, the investigators found the geographic configuration of region presents a special challenge to atmospheric prediction and analysis. The New Jersey and Long Island coasts are approximately at right angles to each other; additionally Long Island Sound separates Long Island from the mainland of Connecticut. The various bodies of water in the region (Atlantic Ocean, Long Island Sound, New York Harbor, Jamaica Bay, etc.) have different surface temperatures. In addition the urbanization of the New York area can modify atmospheric flows.

Apart from land-sea breeze phenomena mesoscale wind fields in general are very important in influencing the coastal and coastal ocean processes. Considerable attention is being

given, for example, to the effect of wind on driving and directing freshwater plumes from rivers entering the ocean. This has many implications for cross continental shelf transport (Lohrenz 1998).

Macroscale Climatology

The location of the coast in the world determines in large part its overall climate. A first order classification of coasts on this scale would include tropical windward coasts, tropical leeward coasts, mid- and high-latitude windward coasts, mid- and high-latitude leeward coasts, and ice-influenced coasts. Each of these categories would be modified according to whether or not the hinterland of the coast contained mountains. Examples of climate data from such categories are given in Table 1. Walker et al. (1987) quote other ways of classifying coastal climates.

Under the classification suggested here the extremes for high precipitation are seen in the tropical and mid-latitude

windward coasts with mountains such as, respectively, on the island of Maui and other islands in Hawaii, and the PNW of the United States. In the case of the north coast of Maui, Hawaii, onshore moist tropical air is lifted up and cooled against the mountains giving rise to some of the world's highest precipitation values. Similar orographic effects occur at the coast of the PNW but here it is moist, mid-latitude Pacific air that is uplifted often during mid-latitude storms, which provides intense precipitation. The extreme for low precipitation is found on tropical coasts on the western sides of continents, as for example, on the coast of Peru. Air flows down the mountain sides of the Andes mountains in Peru and northern Chile and thus is warm and dry when it reaches the coast. More importantly this coastline, and others in this category, has a cool ocean current offshore. Upwelling of cold water gives rise to fog that is often the only source of precipitation in this climate. Ice-ocean boundaries are not considered to be coastlines by some (Walker et al. 1987) but since they form a distinctive interface on the Earth's surface they will be briefly mentioned here. Thus the "coasts" with

Coastal Climate, Table 1 Climate data for selected coastal areas

Tropical	Location	Latitude (Deg Min)	Longitude (Deg Min)	Elevation (m asl ^a)	Mean annual temperature (°C)	Mean monthly temperature Range (°C)	Annual precipitation (mm)

the lowest temperatures are those formed by the meeting of ice masses and the sea such as the Greenland and Antarctic ice cap coasts. Such coasts are often marked by strong, katabatic winds blowing from the ice cap. Katabatic winds are winds formed from cold, relatively dense air flowing down a topographic feature. The climate of the other categories of coasts is intermediate between the extremes described here.

One of the most important features of coastal macroclimate is the storm. Both tropical storms (hurricanes) and mid-latitude storms or cyclones heavily impact the geologic, biologic, and human dimensions of a coast. Sometimes it is the presence of the coast itself that helps cause or enhance the storms. Cyclogenesis is enhanced, for example, at the east coast of the United States as upper-level disturbances cross the Appalachian mountains and then cross the strong baroclinic zone of the atmosphere near the coast. At the coast, the cyclones flow parallel to the landmass in winter and a strong cooling of air on the landward side leads to the formation of macroscale fronts (Rotunno 1994).

Considerable time is spent researching the frequency and magnitude of coastal storms. Waves generated by mid-latitude storms, for example, are responsible for much of the coastal erosion that occurs along the Atlantic coast of the United States. Dolan et al. (1988) found that at this location, the five-month period December through April had 63% of all the storms for the area. They also found a systematic increase between 1942 and 1984 in the number of storms occurring in May and October resulted in the lengthening of the storm season and a more abrupt transition between the winter and summer storm regime. The authors were able to construct a map of the mean cyclone track and frequency of all the mid-latitude storms in their data set that produced significant waves at Cape Hatteras. The storm track runs Southwest to Northeast following the coast of the Carolinas and continuing out to sea at Cape Hatteras. Locally the storms following this track are called Nor'easters and they often do considerable damage to the coast. The secular variation of such storms is very important. Hayden (1981) discovered that in the early years of the twentieth century there was a trend toward increased cyclone frequency over marine, as opposed to continental, areas of the Atlantic US coast. He also found decadal changes in coastal cyclogenesis with a maximum in the record up to 1978 occurring in the 1950s.

It is possible that decadal changes in the frequency of storms whose predominant wind directions is different can lead to marked geographic effects. At Hog Island, Virginia there is a clear dynamic coastline change pattern: erosion occurs on the north when accretion occurs on the south, or vice versa. This kind of cyclic process of coastline changes may repeat every 190 years on Hog Island. Currently, the southern part of Hog Island just ended the erosion processes, while the northern part just ended the accretion processes. It is hypothesized that the changing geography of the island on

this timescale may be related to the frequency of storms that either have winds with a predominant northeasterly or southeasterly component.

Damage to coasts is also done by Tropical Cyclones that go by different names in different parts of the world – hurricanes, for example, in the Atlantic and typhoons in Southeast Asia. For a tropical cyclone to be called a hurricane there must be a sustained wind of 33.5 m/s (75 mph) or more. Such systems can have diameters exceeding 300 km. Very large typhoons in the western North Pacific can have diameters up to 3000 km and are sometimes called super-typhoons. Hurricanes are placed into five categories in the United States. Category 1 has wind speeds of 119–153 kph; category 2, 154–177 kph; category 3, 178–209 kph; category 4, 210–249 kph; and category 5, has wind speeds in excess of 249 kph. In the following discussion, I will use the term hurricane as being synonymous to tropical cyclone.

Hurricanes are features of coastal climate mainly during the late summer and autumn seasons since they depend upon high Sea Surface Temperatures (SSTs) as one factor in their initial formation. Hurricanes impact the tropical, subtropical, and mid-latitude coastlines that are mainly on the east coasts of continents or coasts that face south in the Northern Hemisphere and vice versa. Hurricanes usually weaken after passing the coastline and moving inland because they depend upon the warm moist ocean surface for their energy. Besides high winds the storms are noteworthy for bringing large quantities of rain to the coast. Sometimes tornadoes are spawned as well. Hurricanes represent an interesting interaction between meso- and macro-climatology since their formation and track once formed is often a function of the macroscale features such as upper atmosphere wind fields. Much coastal damage is done by the interaction of the hurricane with the ocean. The resulting formation of storm surges brings extra high flows of ocean water over the coastline. The storm surge of a category 5 hurricane could be 5.5 m (18 ft) above normal sea level.

As with mid-latitude cyclones, interdecadal variability in frequency is well marked in hurricanes. Hurricane frequency in the Atlantic decreased from the 1890s to the 1920s and 1930s, increased during the 1940s to 1970s, and then decreased in the last part of the twentieth century (Riehl 1987). The latter decrease coincided with the development of much coastal property in the Southeastern coast of the United States.

Ice-influenced coastlines have their own interesting climatological features besides the katabatic winds already mentioned. An interaction between macro and mesoscale events gives rise to strips of open coastal water surrounded by ice-covered ocean. The open water areas are called polynyas and they typically open and close over the time period of a few days. They are partly formed by coastal winds pushing the ice offshore and are associated with a complex set of water and atmosphere density and flow interactions (Chapman 1999). The polynyas, sometimes called leads, are large sources of

sensible heat to the atmosphere in winter with heat fluxes locally exceeding 500 W/m^2 . In summer, the comparatively low albedo of the open water compared with that of nearby ice allows the absorption of solar radiation that warms the water. The fractional lead coverage in the Arctic Ocean as a whole is 1% in winter and greater than 20% in late summer (Curry and Webster 1999).

There are also phenomena of dynamic climatology existing where coastlines are backed by mountain areas. Rotunno (1994) describes how Kelvin waves may propagate along the basin-wall-like sides of an ocean basin such as at the Pacific coast of North America. Here also strong alongshore jet streams have been documented as a result of the mountains. Phenomena that appear similar to flow separation in classical fluid dynamics have been found to occur in the lee of capes and other coastline salients.

Temporal Climate Variability in Coastal Climates

All coastal climates are subject to climate variability on a variety of timescales. The presence of the ocean water has a moderating effect on the climate of the nearby land at all the timescales. Climate variability at coastlines is therefore usually less than that in interior continental landmasses but can still be significant especially at the longer timescales. We may examine an example from the PNW of the United States to demonstrate the kinds of climatic variability that can occur at, or near, a coast over a variety of timescales.

Major changes in the climate of the PNW from glacial to interglacial have been described by Warona and Whitlock (1995). The extreme glacial climate, a little inland from the coast, had a mean annual temperature that was likely to have been 7°C lower than today with the January temperature 14°C lower. Conditions were also probably drier than today with the Polar Front jet stream flowing well to the south. After the last retreat of the ice the climate was warmer. Between 10,000 and 5600 BP (Early Holocene) temperature is believed to have increased and effective moisture decreased as summer droughts became a climatic feature associated with an expansion of the subtropical high pressure in the eastern Pacific Ocean. On the next timescale down, some cyclic coastal climatic behavior has been suggested. Sediment cores from anoxic basins reveal a 60–70-year cycle of warming and cooling over the past 1500 years (US GLOBEC 1994). The last cycle in this pattern, which ecologically is associated with sardine dominance over anchovy and vice versa, is seen with warming around 1925, cooling at 1948, and a return to warming about 1977. Ware and Thompson (1991) regard the 60-year cycle in Southern California data as being consistent with their belief that pelagic fishes are responding to a 40–60-year oscillation in primary and secondary production that, in turn, is being forced by a long-period oscillation in wind-

induced upwelling. Trenberth (1993) reviews coupled General Circulation Model (GCM) output and suggests, under current projections of CO_2 increase, the western coast of North America is expected to warm by about $1.0\text{--}1.5^\circ\text{C}$ by the year 2030 and that northern regions will warm more rapidly than southerly regions. The hydrologic cycle is expected to intensify by about 10% leading to greater amounts of evaporation and precipitation. Trenberth (1995) has also suggested that the relative frequency of the El Niño mode in the past decade “may well be one of the primary manifestations of anthropogenic global warming.” There are also interdecadal scale variations in PNW coastal climate. Mantua et al. (1996) described a Pacific Decadal Oscillation (PDO) in SSTs that has many implications for salmon production. It has been shown that the PDO manifests itself in coastal climate by giving rise to four distinct climatic periods. The periods are 1896–1915, wet and cool, 1915–46, dry and warm; 1947–75, wet and cool; and 1976–94, dry and warm. The dominant source of variation on the quasi-quintennial scale is related to the El Niño–Southern Oscillation (ENSO). Low Southern Oscillation Index (SOI) values (El Niños) are correlated with reduced precipitation (Redmond and Koch 1991), snowpack and streamflow in the PNW (Cayan and Webb 1992). The PNW also tends to display warmer winter temperatures and drier than usual winters under El Niños conditions (Redmond and Koch 1991). At the opposite end of the oscillation Kahya and Dracup (1993) are among several investigators to demonstrate that high precipitation and high streamflow values in the coastal PNW are often associated with La Niña years. Superimposed on ENSO-scale climatic variability is the variability on the interannual and shorter timescales such as the passage of individual mid-latitude cyclones and anticyclones.

Future Research

There is an unlimited amount of work to do on coastal climates. Working through the scales we may suggest the following areas of important research. First, it would be interesting to document the differences in the surface energy budget values across the different surfaces of the subcomponents of the shoreline – barrier island, marsh, lagoon, etc. Second, it is important to find out what are the interactions between the mesoscale and macroscale events with respect to coastal climates. How, for example, do sea breeze fronts affect other weather systems occurring inland? Much more has to be found out about the effect of varying SSTs on weather systems passing over them. This is particularly the case where SSTs show a large range of different values over a short distance. The Gulf Stream ocean current and areas of coastal upwelling water are cases in point. There are many local dynamic features that need investigation such as the trapping

of atmospheric waves under marine temperature inversions and low-level coastal atmospheric jet streams. Interdecadal variation in the climatic variables of coastal climate must be established and, if possible, explained. This is important because of the huge amount of coastal development that has happened and will continue to occur worldwide. Finally, the affect of potential global climate change on coastal climates over the next 100 years must be studied. This topic has not received too much attention so far because the global climate models tend to operate at a coarser spatial scale than one that allows a coast to be specifically considered.

Coastal Currents

Guy Gelfenbaum

Coastal and Marine Geology Program, US Geological Survey, Menlo Park, CA, USA

Introduction

Coastal currents are coherent water masses in motion that are found in the region between the coastline and the edge

of the continental shelf. Coastal currents are important because the coastal zone is the place where most nutrients, pollutants, and sediments are introduced into the ocean, and where most larvae are generated and dispersed. Coastal currents are responsible for the transport and dispersal of these biological, chemical, and geological tracers in the water. For example, predictions of the advection and diffusion of spilled oil is dependent upon knowledge of the currents near the coast. Coastal currents often are considered as being made up of two components, alongshore, or parallel to the coast, and cross-shore, or perpendicular to the coast. Away from the influence of inlets or river mouths, cross-shore flows are typically weaker than alongshore flows, yet the larger gradients in cross-shore properties make the cross-shore flows better at redistributing those tracers. In addition, if a current is periodic, such as a tidal current, even though it may be quite strong, it may not result in significant net transport. A non-periodic event-driven current such as from a storm may result in a significant net transport. Some currents that are persistent and result in significant transport of water are named after an adjacent landmass, such as the California Current and the Kuroshio Current. In general, currents are classified by the processes that form them (Wright 1995). Some of the most important currents that exist near the coast outside of the surf zone include (1) wave-driven currents, (2) tidal currents, (3) wind-driven currents, and (4) buoyant plumes.

Types of Coastal Currents

Wave-Driven Currents

Periodic water particle movements are associated with the passage of wind-generated surface gravity waves. The back and forth currents due to waves have a relatively short period, up to about 20 s. The horizontal orbital velocity of water motion is a function of wave amplitude, wave period, wavelength, and water depth (Komar 1998). According to linear wave theory, the water motion under waves in deep water is circular, with horizontal motions being comparable to vertical motions. The diameter of the circular motion decreases exponentially with water depth, so that in deep water, the influence of the surface wave can no longer be felt. In intermediate water depths the motions are elliptical, becoming smaller and flatter as the bottom is approached, and in shallow water the water motions are back and forth. In deep water, where linear wave theory is best applied, there is no net transport of water due to the passage of a wave. In shallow water, however, linear wave theory breaks down. According to nonlinear Stokes theory, the velocity magnitude is increased and the duration shortened under the crest of the wave, and the velocity magnitude is decreased and the duration lengthened under the trough. The result of this asymmetry in orbital motion is a

non-periodic current, or mass transport in the direction of wave propagation, which is called Stokes drift. This mean current can be large for large amplitude and short period waves, but is a small fraction of the instantaneous wave speed, only a few centimeters per second for long period swell.

Tidal Currents

Tides and tidal currents in the ocean basins are produced by the interaction of a rotating earth with the gravitational forces of the moon and the sun (see “► Tides”) (Mofjeld 1976; Bowden 1983). These oceanic tides impinge on the continental shelf and produce sea-level oscillations and currents in the coastal zone at tidal frequencies. The dominant fluctuations are either semi-diurnal (twice a day), diurnal (once a day), or a combination of the two. For example, on the East Coast of the United States the tides are semi-diurnal, whereas on the Gulf Coast they are diurnal. The difference is due to the interaction between the forcing and the natural frequencies of the tidal basin. Most coastal environments also have longer variations in the tides and tidal currents with periods of about 2 weeks. These fortnightly variations result in stronger spring tides and weaker neap tides. Tidal heights (up to a few meters) and tidal currents (up to several tens of centimeters per second) are periodic, thus they result in little net transport, despite excursions of several kilometers per tide. The horizontal component of tidal currents on the continental shelf tends to change direction and amplitude during each tidal cycle. An arrow denoting the current's speed and direction would trace an ellipse with each tidal period. If the direction of the current is restricted by a boundary, as near a coast, then the ellipse will become more elongated, with the long axis aligned parallel to the coast. The speed of a tidal current may increase when the current goes around a headland, passes through a restriction, or passes from deeper to shallower water.

Wind-Driven Currents

The drag of the wind on the sea surface results in the formation of waves and in the generation of a surface current. The wind-generated current is strongest at the surface and decreases with depth. The magnitude of the surface current depends on the wind speed and on the roughness of the sea surface due to waves, which effects the transfer of energy from the wind to the water. Based on field observations, the magnitude of the surface current is approximately 3% of the wind speed and the direction of the wind-driven current is nearly aligned with the direction of the wind, but not exactly. Due to the rotation of the earth, the Coriolis force causes the wind-generated current to veer to the right of the wind in the Northern Hemisphere and to the left of the wind in the Southern Hemisphere. Various theories predict that the surface current will be directed between 10° and 45° to the right (left) of the wind in the Northern (Southern) Hemisphere, and

that the current vector will rotate further to the right (left) with increasing depth below the surface. This rotating current direction and decreasing speed with depth is known as the Ekman spiral. The total transport averaged over the entire Ekman spiral is at right angles to the direction of the wind and is known as Ekman transport. The turning of the upper layer is reduced, however, in shallow water where the water depth is less than the Ekman depth.

Upwelling and Downwelling Circulation

When the wind blows parallel to the coast and the wind-driven Ekman transport is away from the coast, then the water near the coast will set down causing a lowering of sea level. The sloped sea level will induce an onshore-directed pressure gradient, which when balanced against the Coriolis force will lead to a shore-parallel geostrophic flow in the same direction as the wind beneath the surface Ekman layer. In addition, water near the coast will rise, or upwell, to replace the surface water that is transported offshore. Upwelling circulation is very important because it brings cold, nutrient-rich water from depth to the surface, which can enhance biological productivity. Many of the largest producing fisheries in the world occur in regions of coastal upwelling. Downwelling flows result when the wind is in the opposite direction, causing onshore-directed surface Ekman transport. In the downwelling case, sea level rises against the coast as surface waters are brought from offshore to onshore. In some cases, there can be an interaction between the shore-parallel wind-driven flow and the upwelling or downwelling waters that enhances the coastal flow. As an example, Korso et al. (1997) described how cold upwelled water along the coast of Oregon and southward-directed wind-driven surface currents interact resulting in an increased coastal jet occurring along the upwelled front.

Buoyant Plumes

Currents arise in the coastal ocean from the flow of freshwater out of rivers and estuaries. Currents result from both the difference in the height of the water between the river and the ocean and from the density difference between the fresh water and the salty ocean water. Upon entering the ocean, the positively buoyant plume will spread laterally on top of the ocean water and thin. After leaving the confines of the river or estuary, the plume will also be acted on by the Coriolis force. The degree of turning of the plume due to the earth's rotation depends on the width of the river mouth, the thickness of the plume, and the Coriolis parameter, which varies with latitude (Garvine 1987). The boundary of the plume where the water density changes rapidly is known as a front. Fronts are important because they mark zones of flow convergence. Plume currents can be affected by existing tidal currents and by the wind. For example, Stumpf et al. (1993) observed a buoyant plume move at speeds of up to 11% of the wind speed. The

enhanced speed of the plume relative to normal surface drift is due to reduced friction between the buoyant plume and the underlying ocean water.

Coastal Currents and Boundaries

Regardless of their origin, coastal currents are effected by their proximity to a boundary, either the seafloor or the atmosphere. Boundaries tend to modify ocean currents through the action of friction. The regions, or layers, in which currents are modified are called boundary layers. Boundary layers near the bed and near the surface can be 5–20 m thick, so on the inner and middle continental shelf, the dynamics of the boundary layers can make up a significant percentage of the water column. In the bottom-boundary layer the flow depends not only on the near-bottom current, but also on the presence of surface gravity waves. This *wave–current interaction* (*q. v.*) tends to modify the near-bed flow. Currents in the bottom-boundary layer can also be complicated by the presence of density stratification and bed morphology (see “► [Shelf Processes](#)”).

In a narrow zone immediately adjacent to the coast, near-shore currents result when wave asymmetry and breaking cause significant mass transport of water in the direction of the shore. Important nearshore currents include undertow, rip currents, and longshore currents (Komar 1998) (see “► [Surf Zone Processes](#)”).

At the outer boundary of the coastal zone, open-ocean currents flowing along the continental slope can at times influence coastal currents. For example, ocean currents such as the California Undercurrent off the US west coast can influence shelf currents by impinging onto the shelf, by entraining water from the shelf, or by inducing flow on the shelf through pressure gradients between the two water masses.

Measurement Techniques

Ocean currents are studied experimentally, through field measurements, and theoretically, through the use of mathematical models. Currents are measured with a variety of instruments, including mechanical rotor-type, electro-magnetic, and acoustic current meters. The choice of which current meter to use depends on among other things the environment in which the measurements are made. In the surf zone, currents are typically measured by mounting electro-magnetic current meters to fixed poles jettied into the bottom. Divers deploy the current meters and the data are logged in real-time through a cable to shore. Shelf and slope currents are measured using current meters on a mooring with a weight on the bottom to anchor the mooring in place and a float at or near the surface to hold the mooring

vertical. Alternatively, current meters are placed on a tripod, a pyramid-shaped frame that sits on the bottom. Current meters deployed on the shelf and in deeper water are self-contained, requiring an underwater power supply and data acquisition system to store the data until the instrument is recovered. In the past decade acoustic current meters that provide a profile of currents through the water column, as opposed to at a single point, have been used extensively to provide detailed information on coastal currents.

Coastal Dynamics

Nils-Axel Mörner
Paleogeophysics and Geodynamics, Stockholm, Sweden

Definition

Coastal dynamics refers to physical processes (dynamic factors) like waves, wind, currents, and sediment supply that affect and shape the coastal morphology independently of changes in sea level or land level (Fig. 1).

Introduction

The shorelevel is the point where the land level and the sea level cross each other. The morphology of the shore depends on several factors.

The tidal cycle records the daily variations between low-tide and high-tide (Melchior 1978), which the shore morphology is adjusting to.

For the trained eye of a sea level specialist, it is usually possible to identify the mean sea level and high-tide level with an accuracy of a few centimeter (Mörner 2010).

The position and variability of the shorelevel is determined by several different dynamic, oceanic, and land level factors, as illustrated in Fig. 1. Changes in any of these variables will lead to a change in the position of the shorelevel in time and space.

The coastal dynamic factors affect, shape, and re-shape the shoreline, either regardless of what happens with the land and sea levels or in interaction with such changes (Fig. 1).

For meaningful analyses of sea level changes and coastal evolution, it is necessary to consider all the factors illustrated in Fig. 1. Ignoring to do so, may lead to unfounded statements and conclusions with respect to sea level changes and coastal protection.

The study of coastal dynamics has a vital mission to fulfil, and it has grown into a successful international organization (e.g., CD 2017).

Tides and Multi-decadal Cycles and Oscillations

Besides the daily, monthly, and annual tidal cycles and the 18.6 years lunar tidal cycle (Melchior 1978), there are also longer-term cycles like the 60-years cycle (Chambers et al. 2012; Parker 2013; Hansen 2015) and the oceanic multi-decadal “oscillations” (the Pacific Decadal Oscillation, PDO; the North Atlantic Oscillation, NAO; Atlantic Multi-decadal Oscillation, AMO; etc.) to consider.

The existence of multi-decadal cycles and oscillations implies that our analyses must extend over several cycles in order to be able to record true mean values.

This is illustrated in Fig. 2 with respect to the 18.6 years cycle covering two full cycles (Mörner 2010). The trend over the last 9 years is a fall in sea level by about 6 cm, while the true mean sea level change over the entire 49-years period is zero (± 0.0 cm).

The Main Coastal Dynamic Variables

There are several different coastal processes, which are capable of changing the coastal conditions and shore morphology independently of changes in sea level or land level (Fig. 1). Sometimes, however, the dynamic changes occur in

Coastal Dynamics, Fig. 1

Many different variables affect the stability of the land/sea interface (the shoreline). They fall within three major groups of changes; the coastal dynamics, the level of the land surface, and the level of the sea (modified from Mörrer 2010). For proper sea level analyses, it is fundamental to understand and consider all variables involved in shore deformation in time and space

Coastal Dynamics, Fig. 2 Changes in annual mean-high-water level (MHWL) along the French Guiana–Surinam coasts from 1958 to 2006 (redrawn from Gratiot et al. 2008). The inter-annual changes in sea level

exhibit a clear 18.6 years' tidal cycle where the mean value has remained virtually stable throughout the entire 49-years period

mutual interaction with changes in ocean level or land level. The coastal dynamic factors deform the shorelevel or point of sea/land interface laterally (Fig. 3) in opposite to the change in sea level or land level, which deforms the shorelevel vertically upward (sea level rise, land level fall, or sediment compaction) or downward (sea level fall or land level rise).

Coastal Erosion

Erosion of coastal segments may be driven by several factors, and is, by no means, a straightforward indication of sea level rise. This is also the case at the deformation of the so-called “Bruun equilibrium profile” in shore morphology (Bruun 1962; Schwartz 1967).

According to Science Daily (2017), “coastal erosion is common phrase referring to the loss of subaerial landmass into a sea or lake due to natural processes such as waves, winds and tides, or even due to human interference.”

Active coastal erosion implies a constant lateral re-adjustment of the position of local sea level.

Silting Up

When the sediment supply is strong, the sediments may grow vertically by silting up as well as horizontally by coastal progradation.

As a consequence, the land/sea interface may become displaced.

Coastal Dynamics, Fig. 3 Coastal dynamics deform the shore laterally (horizontally), while the changes in sea level or land level deforms the shorelevel vertically

In river deltas, there is a continual sediment accumulation forcing the shore to move seaward.

The motion of sediments is a key factor for coastal environment and its dynamical changes in time and space (e.g., Sheng 1986; Soulsby and Whitehouse 1997).

Sediment Supply

Some coastal segments are fed by a constant sediment supply from nearby rivers. Changing the sediment supply may lead to sediment starvation of a beach. Due to changes in runoff (below), the sediment supply may change and thereby generate sediment starvation.

If the shore morphology is changed, the position of mean sea level may become displaced laterally, despite sea level remaining constant.

Continental Runoff

Changes in the supply of water and sediments in a river system may generate strong effects in the adjacent coastal systems (e.g., Milliman and Ren 1995). Delta areas may starve in parts or as a whole. Beach fed by constant sediment supply may starve, and even disappear.

Building of large river dams or diverting water for irrigation affects the amount of water and sediments reaching the delta area.

In Bangladesh, for example, large dams decreased the water masses reaching the sea, and the salinity increased, which was misunderstood in terms of a sea level rise.

Natural changes in the runoff via rivers are controlled by alternations in the catchment area between wetter and dryer periods.

Satellite altimetry records a higher sea level over the eastern part of the Mediterranean Sea and the Black Sea. This is a function of increased runoff from the huge catchment area of the Black Sea and has nothing to do with any rise in sea level (Mörner 2005).

Changes in Wind Direction

Changes in wind direction, especially the prevailing wind direction, may significantly affect the coastal conditions, and lead to significant deformations of the shore morphology. Even the direction of long-shore drift may change. We have numerous examples of this all over the globe. As a result, the line denoting the sea/land interface may become displaced laterally (landward or seaward) without any real vertical change in sea level.

Coastal Currents

The coastal currents are essential for the local to regional shore stability (e.g., Gelfenbaum 2005). The coastal currents may change their course because of factors like wind direction, silting up, sediment supply, water runoff, and, not least, human interference with the coastal conditions. This may generate significant shoreline deformation in the horizontal dimension.

Storms

A strong or extremely strong storm may rapidly deform a shore. Some beach-ridges were formed by a single storm. The extreme waves may at the same time cause severe erosion. With reorganization of the shore morphology, the point of sea/land interface would become displaced in horizontal dimension.

Hurricanes and Cyclones

Hurricanes or cyclones are extreme storms that hit a coast with very strong wind and wave forces. The coastal destruction may be strong, even disastrous. The shore morphology may become seriously altered with a new land/sea configuration, despite the actual sea level remaining constant.

Tsunamis

Tsunami events are characterized by high and fast-moving waves. The big events may sometimes rise to really destructive wave dimensions (e.g., the 2011 event in Japan, the 2004 event in the Indian Ocean, the 1755 event at Lisbon). The coastal damage and reconfiguration of the land/sea distribution may become very severe. Tanaka et al. (2012) recorded extensive coastal deformation at the 2011 tsunami event in Japan, just to refer to one recent example.

Human Interference

Human activity may often lead to severe coastal damage and erosion. Just the very strongly increase in beach and shore utilization for pleasure and tourism put pressure on the coastal stability.

Clearance of mangrove vegetation often leads to severe erosion, and has become serious problem in recent decades.

Removing the protecting mangrove vegetation generates a strongly increased vulnerability to storm destruction.

Quarrying of shore sand, beach-rock, corals, and eolianites are all destructive activities for shore persistence.

Even the massive removal of sea cucumbers from the shallow waters off the beaches in Fiji led to removal of sand, which opened the shore for erosion.

Our regulation of rivers affects coastal runoff and sediment supply to the sea (above) affecting the coastal shore stability.

Building of protecting jetties and seawalls often lead to unforeseen effects including increased erosion.

Summary

The stability of a shore in time and space depends of several different factors. Besides changes in sea level and in land level, there are a number of dynamic factors operating. Those factors may generate significant changes in shore morphology and shore position without being linked to any changes in sea level (eustasy) or land level (compaction or tectonics).

Synonyms

Beach erosion; Shore erosion; Coastal abrasion

Definition

Erosion (from Latin *erosio*, to wear, to wear away) refers to surface processes acting to remove material. In the coastal zone, the wearing away and transporting away of sediment particles and rock fragments are known as *coastal erosion*. *Coastal erosion* applies to the entire coastal zone (e.g., Jolliffe 1982; Pranzini and Williams 2013), i.e., the zone extending from the offshore environment to the coastal onshore area, but primarily refers to the inland displacement of the point of sea/land interface (the mean sea level). The loss of shore deposits (e.g., beach and dune deposits, marshlands) and landmasses (e.g., rocky headlands) into the sea is driven both by natural processes that include waves, wind, currents, and slides and by human interference with shore processes.

Introduction

The coastal shape or assemblage of landform configurations is conditioned by the extent geology, ground relief, and shoreline character (Owens 1982). The character or nature of the shore is developed in a wide spectrum of landforms from equatorial to polar coastal segments (Valentin 1952; McGill 1958; Carter and Woodroffe 1994). Many coastal landforms are ubiquitous (e.g., beaches, dunes, spits and bars, cliffs), but some specialized forms are latitudinally dependent as in the case of coral reefs, beach rock, mangroves (Spalding and Grenfell 1997), and boulder beaches on polar (glacial and paraglacial) shores (e.g., John and Sugden 1975; Carter and Woodroffe 1994). These kinds of prevailing coastal conditions set the coastal character that is in a more or less constant state of flux. Those conditions, which are likely to change over time for a number of reasons (below), may initiate coastal erosion or re-shaping of the shore. Study of erosion and sediment redistribution is called *coastal morphodynamics*.

The change from coastal stability to coastal erosion is caused by many different processes that may involve neotectonics, changes in prevailing wind direction, deviation or reinforcement of coastal currents, reestablishment of equilibrium profiles (e.g., Dean 1991; Dean and Dalrymple 2004), sea-level rise, sea-level fall, exceptional storms, hurricanes/cyclones/typhoons, and tsunami events (below).

Origin of Coastal Erosion

A suite of different physical processes are involved in the overall concept of coastal erosion, which is a catchall term for many different specific processes. *Coastal abrasion* refers to the mechanical erosion by particles in the moving waves and occurs when breaking waves containing rock

particles (sand, gravel, stones) erode the shore or headland. The correlative geomorphological process is also known as *corrasion*. When waves cause particles and pieces of rock by collision, grinding and chipping to become progressively smaller, smoother, and rounder, it is termed *attrition*. Bedrock surfaces may also become weathered and eroded by *solution* (especially in the case of sandstones and limestones) and *corrosion*. *Hydraulic action* and fracturing occur when waves (and wind) compress air or water into cracks. In combination with freezing and thawing, this may lead to the fracturing off of rock fragments.

All coastal segments are in principle susceptible to erosive forces that lead to the displacement of sediments and rocks. Of the several processes and factors that may generate coastal erosion and remodelling of the shoreline, most erosion is often accompanied by the interaction of multiple biophysical processes. While shore cliffs are in a more or less permanent stage of erosion, other coastal segments may move into (or out of) an erosional condition due to changes in ambient coastal conditions that may be short termed or relatively long lived. The processes involved in such changes (below) are of primary interest for meaningful interpretations of observed coastal erosion (e.g., Pranzini and Williams 2013; Mörner 2015).

Changes in Prevailing Wind Direction

Variations in prevailing wind directions may alter, or even revert, active shore-building conditions by affecting longshore drift. Erosion in updrift shore segments is often balanced by deposition in downdrift segments, but along some coasts, there is a decrease in sediment load of the longshore drift because sediments are lost offshore beyond the depth of closure by cross-shore currents (e.g., Finkl 2004). Because sediments in these cases are effectively lost from the coastal sediment budget, shorelines so affected are in retreat (retrograde). In the opposite situation where shorelines are prograding, the sequence may take the form of a complicated braid of shorelines where one system is cutting the previous one and where even the direction may revert as a function of changes in prevailing wind directions (e.g., Schröder 2015; Hansen et al. 2016). Under specialized conditions where there are areas of very high land uplift, as occurs in northern Sweden with an uplift rate of 10 mm/yr, erosion of an older beach-ridge system has been observed in progradational systems which at first seems counterintuitive.

Changes in the prevailing wind direction have been recorded at many coastal sites. The longest continual record of changes in prevailing wind direction covers 10,000 years and is established by alternations in longshore drift, with shoreline erosion updrift and downdrift building out of beach ridges in southwest Sweden (Mörner 1980).

Changes in Coastal Currents

The term *coastal currents* refers to water masses that are in a roughly shore-parallel motion between the shore and the shelf break (Gelfenbaum 2005). In this case, we only consider the currents affecting the shore, however. These currents, which constitute relatively uniform drifts in deeper water adjacent to the surf zone, may be tidal currents, transient, wind-driven currents, or currents associated with the distribution of mass in local waters. Currents that drive coastal morphodynamics and which affect shore processes are linked to winds, waves, tides, and offshore morphology. Longshore currents are driven by waves and winds, generating the longshore drift responsible for the building of beach ridges, spits, and spurs. Tidal currents can modify the coastline and offshore bottom topography. Cross-shore currents refer to currents that are directed perpendicularly (normal) to the shore.

The near-shore currents may change both in force and in direction over time, which may generate coastal erosion and/or reorganization of the shape and character of the beach. Currents, among other factors, largely determine the shape of configuration of the shore and along with waves determine the beach type (Short 2003).

Human interference with coastal (beach) processes due to the construction of seawalls, groins, and jetties along the shore often affect the coastal currents in an unwanted manner, generating increased problems instead of providing coastal protection (Pilkey and Wright 1988; Young et al. 2009; Mörner and Matlack-Klein 2017).

Changes in Runoff and Sediments Supply

Changes in runoff and sediment supply may lead to beach starvation and reorganization of the beach morphology. Lack of adequate sediment supply to maintain a healthy beach often occurs when human constructions decrease the amount of river water flowing to the sea or when climate changes to drier and warmer conditions (e.g., Leader et al. 1998; Walling and Fang 2003; Syvitski et al. 2005; Zhang et al. 2006). This situation has become an accelerating problem today because so many rivers have become utilized for irrigation and dammed for electrical power generation (e.g., Mehta et al. 2012). Major river deltas, deltaic environments, cheniers, and coastal marshlands are sometimes seriously eroded by the changes in river runoff (e.g., Milliman and Mei-e 1995; Wahid et al. 2007; Syvitski et al. 2009; Giosan 2014; Day et al. 2016).

Readjustment of Equilibrium Profile

The motions of the water due to waves, tides, and currents along a sandy coast tend to generate a more or less equilibrated balance between erosion and deposition that shapes the onshore-offshore relief (bottom topography or bathymetry) according to some sort of idealized *equilibrium profile*

(Brunn 1954, 1962; Schwartz 1967). In coastal engineering and geomorphology, this equilibrated shore profile is also known as *active shore profile* (e.g., Beech and Andrews 1993).

There is an extensive literature concerning coastal equilibrium profiles and what effects it may lead to (e.g., Brunn 1954, 1962; Strahler 1966; Schwartz 1967; Dean 1991; Pilkey et al. 1993; Cooper et al. 2000; Andrews et al. 2004; Mörner 2015). The problem is much more complicated, however, than just the reestablishment of an equilibrium profile deformed by sea-level rise. This concept is further discussed below and illustrated in Fig. 2.

According to Andrews et al. (2004): “The Bruun Rule has no power for predicting shoreline behaviour under rising sea-level and should be abandoned. It is a concept whose time has passed” (cf. Fig. 2). This opinion should invalidate previous claims (e.g., Titus 1986; Titus et al. 1991), but by no means is established in the literature, as there still appears to be conceptual value in the cognition of gross shore profile change due to erosion and sedimentation.

Instability of Cliff Sections

Coastal cliffs are steep escarpments at the coastline that form cliffed or abrasion coasts. In many instances these common erosional landforms are very scenic, if not majestic, shores as erosion of the cliff face exposes internal layering and other types of rock formations (e.g., Leary 2014). Coastal cliffs are usually formed in sedimentary bedrock, but they may also occur in thick till deposits in formerly glaciated areas, and in older marine beds, not to forget volcanic formations as well.

Cliffed coasts or *abrasion coasts* refer to coastal segments where wave action has led to the formation of steep, unstable cliffs where waves undercut the cliff at its base. Sudden cliff

collapses (slides and rock fall) are a more or less natural part of active sea cliffs that supply sediment to the littoral drift system. In addition to wave action undermining cliff faces, earthquakes may intensify erosive collapse as occurred, for example, during the M 5.7 earthquake in Christchurch, New Zealand, in 2016 (BBC 2016).

Coastal erosion is perhaps most dramatically expressed in coastal sections marked by impressive coastal cliffs (e.g., Leary 2014). Some examples of these erosional features include The Seven Sisters, Seaford Head, England; The Twelve Apostles, Great Ocean Drive, Australia; Stevns Klint (with the Cretaceous/Tertiary boundary section) in SE Zealand, Denmark; and Etretat, France, just to mention a few.

Bedrock cliffs and undercut notches are often linked to *wave-cut platforms* or *rock-cut platforms* (e.g., Sunamura 2015), in most cases denoting the local high-tide level (as shown in Fig. 1).

Sea-Level Changes

Coastal erosion is often interpreted as a sign of sea-level rise (Brunn 1954, 1962; Schwartz 1967; Titus 1986; Bird 1993; cf. point 4, above). This is not tenable, however (e.g., Andrews et al. 2004; Mörner 2015), because any change in the position of sea level, whether positive or negative, will affect the Bruun equilibrium profile with the potential of generating coastal erosion (Fig. 2). The relation between coastal erosion and sea-level change is far more complicated than suggested in the Bruun Rule, but there are some generalizations that can be made between sea-level stands and coastal erosion deposition. These generalizations occur outside the realm of human interference.

Coastal Erosion,

Fig. 1 Undercut notch in the bedrock with associated wave-cut platform (flat rock surface at the cliff base) grading over into the high-tide level of the sandy beach to the left in the background (Naviti Island, Fiji, photo; Mörner 2017)

Coastal Erosion, Fig. 2 Island wind- and lee-side morphology (a) and erosion/deposition in association with a sea-level rise (b) and a sea-level fall (c), respectively. Indicated on the exposed windward-side of the island (a) are the low-tide level (LT), mean-tide level (MT), high-tide level (HT), and swash limit (WL). When sea-level rises in (b), minor erosion takes place as the shore profile cuts inland. On the island's depositional lee-side, eroded materials are redeposited upward (arrow pointing inland) over previous land surfaces. When sea level falls in (c),

sediments on the shoreface are eroded as the shore profile equilibrates to the new morphodynamic conditions. On the lee-side, the eroded materials are redeposited seaward or down profile. As a result, the former beach is stranded above the new lower tide level and becomes a dry land surface that is exposed to biophysical weathering and vegetative overgrowth, i.e., as observed in the Maldives, for example (Mörner et al. 2004; Mörner 2015), and elsewhere as a general principle.

Because erosion in one segment of the coast implies deposition at another (e.g., Fairbridge 1961; Bird 1995; Mörner 2015), typically in an eroded updrift segment versus a depositional downdrift segment, one can use this morphodynamic balance to ascertain whether sea level is rising or falling.

A clue to modal changes in sea-level may be found in a depositional shoreline segment (e.g., on the lee-side of an island, as illustrated in Fig. 2) downcoast from the erosional site that was assumed to be caused by a change in sea level (e.g., Mörner et al. 2004; Mörner 2015).

Sea-level rise tends to deform the equilibrium shore profile, which may generate some degree of costal erosion (Fig. 2b) depending on the alongshore sediment supply. On the island's lee-side, the eroded sand is deposited in over previous land levels (as marked by an arrow in Fig. 2b). Stratigraphically, this implies that marine sand is deposited over a former land surface. This gives evidence of a sea-level rise (or, alternatively, the result of storm surge deposition).

A fall in sea level will inevitably lead to extensive erosion, by wave and current action, of the previous equilibrium offshore profile (Fig. 2c). Under a falling sea-level scenario, eroded sand will be redeposited at a lower level seaward (as marked by an arrow in Fig. 2c). Materials in the former beach, which had become stranded at and above the former sea-level position, become susceptible to subaerial weathering processes. This provides evidence of a fall in sea level (whether of local or regional dimensions).

Exceptional Storms

Most open-ocean costal segments are impacted by various types of high-energy conditions that feature meteohydrodynamic conditions with large waves, strong currents that often culminate in *storm surges* (e.g., Brennimeyer 1982; Aagaard and Masselink 1999) that can cause extensive erosion. When some storms are exceptionally vigorous and their intensity exceeds normal storminess, they are classified as once in a century storm or one in a thousand year storm. These exceptional storms cause exception coastal erosion. Sedimentary deposits left by these kinds of extreme storms are referred to as *tempestites* (Myrow and Southard 1996). In addition to the erosive impacts of these severe storms, they have potential to damage life and property (NOAA 2017).

A particular coastal storm usually affects only parts or segments of a coast. Local storm impacts depend on a range of properties such as the nature of the shore materials (rock or sediments), degree of exposure to high-energy conditions, and coastal morphology. The same storm may cause severe destruction in one part of the coast, while in another part of the same coast, there may be only vague or insignificant impacts (Mörner 2015). Therefore, the degree of local erosion is not a straightforward measure of the severity of the storm as many factors are involved.

Ameliorative effects on coastal erosion are provided by mangrove vegetation that is quite effective in the reduction of *storm surge* (McIvor et al. 2012). Coastal erosion is

Coastal Erosion, Fig. 3 The Sidr Cyclone, which hit Bangladesh coasts in 2007, caused extensive coastal erosion, as evidenced by the exposed tree trunks in living position on the beach at low tide. The horizontal roots, previously covered with mud, indicate that about 80 cm of deltaic muds were removed by the cyclone and that no rise in sea level was involved (Photo at low-tide: Mörner 2009)

Coastal Erosion, Fig. 4 The shore of the Yokosuka coast in Japan before (black line) and after the Tohoku-Oki tsunami. The land/sea boundary configuration as of March 11 2011 was recorded by Tanaka et al. (2012) and here redrawn and modified by Mörner (2015). The coastal remodelling is very extensive.

exacerbated by deforestation of mangrove vegetation such as occurs in many tropical and subtropical coastal regions (e.g., Rahman et al. 2009). The loss of fringing mangrove forests, which protect the shore from erosion, results in a “coastal squeeze” that makes such shore more vulnerable to loss of mangrove sediments (e.g., Truong et al. 2017).

Hurricane-Cyclone Events

Hurricanes or tropical cyclones impact coasts with very strong forces that often modify the shoreline configuration via the processes of erosion deposition. Major coastline readjustments are thus often associated with these high-energy events. The nomenclature used – i.e., hurricanes, cyclones, and typhoons – differs for historical and geographical reasons, with a useful classification scheme to be found on Wikip (2017). The long-term activity trend of these large storms has been much debated. On a global base, tropical

cyclones have remained at about 87 ± 10 events per year. By modelling, Emanuel (2005) claimed: “the hurricane intensity has increased markedly since the mid-1970s.” By observational facts, however, Rojo-Garibaldi et al. (2016) demonstrate that the number of hurricanes from 1750 to 2010 in the Gulf of Mexico and the Caribbean Sea exhibits a decreasing trend toward the present, with anticorrelation to the number of sunspots. This observation has wide implications for understanding of coastal vulnerability to future erosion.

The Bangladesh region is regularly struck by big cyclones, often with tremendous erosional effects. The *Sidr Cyclone* hit the coasts in 2007 causing extensive erosion (Fig. 3) and exposed trees in living position along the beach at low tide. Removal of these coastal sediments was storm induced (Fig. 3) and had nothing to do with any purported rise in sea level (Mörner 2010).

Tsunami Events

Tsunami events usually lead to severe coastal erosion and remodelling of the shore (Fig. 4). The accumulation of redeposited material derived from a tsunami, termed *tsunamite*, is a special type of *tempestites* (Shiki and Yamazaki 2008). The tsunami events of Lisbon (1755), Messina (1908), Indonesia (2004), and Japan (2011) are all notorious for the erosion and remodelling effects onshore as well as offshore (e.g., Fonseca 2005; Tanaka et al. 2012). The Tohoku-Oki tsunami event in Japan (2011) had a maximum wave height of 19.5 m and a maximum run-up of 40 m extending 5.4 km inland (Lario et al. 2016). The erosion and remodelling of the coasts were extensive, as illustrated in Fig. 4 (based on Tanaka et al. 2012).

Human Interference

Human interference with the coast has a long history that was a major factor affecting coastal morphology and shoreline position due to induced erosion. This influence began with early agriculture in the late Stone Age and accelerated with intensified human activities and engineering constructions along coasts in historical time (e.g., Davis 1956). Coastal engineering interference with coastal processes often leads to negative implications for the sustainability of the beach environment (Pilkey and Wright 1988; Young et al. 2009; Finkl and Makowski 2010). On the whole, coastal protection is a complicated matter where consideration has to be given to a lot of different factors, some of which often remain unknown or uncertain. While it seems obvious that fishing utilizing explosives are likely to generate disastrous effects on coastal stability, it seems quite unforeseeable that even the harvesting of thousands of sea cucumbers may lead to severe coastal erosion (Mörner and Matlack-Klein 2017).

Human interference with the coastal runoff (Mehta et al. 2012), the sediment supply (Syvitski et al. 2005), land/sea configuration (Davis 1956), and installation of coastal protection constructions (Young et al. 2009) have a significant, sometimes even dominant, effect on coastal erosion and remodelling.

Summary

Coastal erosion is a key issue in Holocene coastal evolution (Carter and Woodroffe 1994; Davis 2009). However, coastal erosion can be generated by numerous different factors including human interference with coastal process (Davis 1956). Any changes in wind conditions, coastal currents, water runoff, sediment supply, cliff collapses, sea-level change, and episodes of severe storms and tsunamis have the potential of affecting coastal morphology and to affect the position (horizontally and/or vertically) of the shore by erosion or deposition.

Interpret of coastal erosion as a straightforward sign of sea-level rise can be misleading because sea-level fall (like many other natural dynamic processes) may also generate coastal erosion.

Definition

Coastal Erosion Management (CEM) is the dynamic, multidisciplinary, and interactive approach in responding to coastal erosion processes to prevent or mitigate economic and social losses. Ideally, such management should also seek to achieve preservation or conservation of natural habitats. CEM requires a detailed knowledge of coastal processes, sediment behavior, and interchange within the coastal zone (offshore, shore, and inland), and how changes, both natural and due to human activities, alter these controls of erosion (see “► Coastal Erosion” in this volume for more detail). The cycle of CEM begins with the identification of a perceived erosion problem, determining the cause(s) and understanding the erosion processes. This basis then guides planning, preparation, and decision-making as to the appropriate response, considering the time frame of expected results, including monitoring whether or not the solution is working. CEM is one aspect of overall coastal zone

management and usually follows the objective of an informed involvement and cooperation of all stakeholders to assess the societal goals in a given coastal eroding area, and to take actions to meet specific objectives. CEM should seek to balance environmental, economic, social, cultural, and recreational goals over the long-term, all within limits set by the natural dynamics of an area. In the past, erosion management responses often have not been successful for a variety of reasons including quick fixes sought in response to emergency events, or misdirected plans based on cost/benefit analysis, or merely placing sole emphasis on protecting buildings and infrastructure without concern for all other coastal aspects. Such short-term protective projects have increased or shifted the erosion problem, caused loss of habitat including economic drivers such as beaches and dunes, and resulted in more property and people in high-hazard zones, increasing vulnerability to future losses. Future CEM plans can be strengthened by having a broader basis for decision including:

- A long time frame point of view
- A stronger emphasis on the restoration and utilization of natural habitats for protection against erosion
- Planned removal of anthropogenic structures to restore sediment supply
- Factoring in both global and regional changes that will increase erosion problems (e.g., sea-level rise, tsunami potential, El Niño)

The spatial, temporal, environmental, physical, and social knowledge related to the area of interest forms the core of CEM to eliminate or at least minimize coastal erosion.

Introduction

Current projections indicate that coastal erosion processes will reach unmanageable proportions due to increasing urbanization during the on-going warming climate and sea level rise. Coastal erosion processes and their management become much more critical as coastlines constitute some of the most densely populated and developed land zones in the world. That concentration of population isn't likely to decline because the coastal zone is the ideal area for different productive activities (Gracia et al. 2018).

Coastal erosion is a normal process that has been active since land emerged from the sea. A suite of natural process and anthropogenic influences (most of the time interconnected) are involved in coastal erosion, which itself encompasses many different specific processes. Coastal erosion can occur as a slow pervasive process (i.e., due to ongoing subsidence) or rapid during extreme events (i.e., storm waves).

It is important to highlight that coastal erosion only becomes a problem when there is no room to accommodate the occurring changes (e.g., shoreline retreat). In this sense, coastal erosion is not an issue along areas where high, stable grounds back up the coast, but erosion is a severe problem for low elevated areas and uplands underlain by unstable materials, rural and urbanized. No matter the place, rates, and causes, coastal erosion is a process that currently raises a significant hazard to ecosystems and human activities and therefore must to be managed (Rangel-Buitrago et al. 2018).

World megacities (e.g., Jakarta, Manila) are located in coastal zones where the conjunction of geographic, economic, ecological, and historical conditions are attracting people, and stimulating different migration processes. Only during the last half century have world coastline populations recorded values close to 5% of the annual average for urban growth rate (UN-Habitat 2009). Under current and projected climate change scenarios, it has been estimated that along low coastlines, almost 35% of residences, if sited within 200 m from the sea, may be severely affected by erosion-related property losses over at least the next 50 years (UN-Habitat 2009).

All of the above make clear that the world needs sustainable development strategies accompanied by an optimal coastal erosion management. The coastal erosion management choice must be a function of a series of variables that include: erosion severity, causes, property rights, funding, legislation, and coastal use. In the same way, CEM must consist of all available knowledge, techniques, infrastructure, and institutional-political tools required to minimize or eliminate coastal erosion related impacts.

Coastal Erosion Management Approaches

The typology of coastal erosion management approaches can be summarized in five categories as follows.

Protection

The traditional approach to managing coastal erosion was to address the problem only at the point of its attack, and to out engineer Nature. And the objective was primarily to protect the fast-land property, be it buildings or farm land. Protection of property is still the driving force in CEM, and related issues such as disruption of sediment supply, beach loss, and habitat destruction are not addressed. This approach consists in the preservation of vulnerable areas (i.e., population centers, economic activities, and resources) by means of constructing hard structures, or alternatively soft protection measures which does include beach restoration. Both hard and soft approaches seek to eliminate or mitigate erosional damage to the coast by use of barriers to reduce wave impact and control hydraulic processes that influence sediment transport (Fig. 1).

The measures to be applied may be summarized in four specific structural solutions that can be developed stand-alone or in combination, depending on the particular conditions of the coast where they will be applied.

Hard Defenses

This approach has been used for CEM since ancient times. Structures are built of different kinds of materials (i.e., rocks, wood, concrete, steel), either parallel or perpendicular to the shore, to provide a barrier between sea and land that resists wave energy or to trap and accumulate sediment. Shore-hardening structures include:

Breakwaters: Structures placed onshore and offshore, generally constructed of hard materials, and designed to absorb wave energy before the waves reach the shoreline (Fig. 1a). These structures are necessary to protect harbor entrances but should have limited application for beach protection, because they disrupt lateral sand transport.

Groins: Structures that extend perpendicularly from the shoreline with the design purpose to trap and hold sand, thereby nourishing the beach compartments located between them. They cut the longshore transport of littoral drift.

Revetments and riprap: Shore-parallel, sloping features which break up or absorb the energy of waves but may let water and sediment pass through (Fig. 1b). Revetments are made of concrete or shaped blocks of stone laid on top of a layer of finer material. Riprap consists of layers of hardrock boulders with the largest, often weighing several tonnes, on the head. Riprap has the advantage of good permeability and looks more natural; however, these structures are in the sea-wall family with the same detrimental effects. Their permeability can contribute to piping which contributes to the wall's sinking, requiring new material to be added.

Bulkheads and seawalls: Shore-parallel walls designed to hold bluffs and banks by completely separating land from water. Bulkheads act as retaining walls, keeping the earth or sand behind them from crumbling or slumping. Bulkheads are sometimes called "sand retention systems." Seawalls are primarily used to resist wave action and fail for a variety of reasons including cutting off the sediment supply, steepening of the beach profile, and causing wave reflection and refraction that cause scour erosion in front of the wall, and increased erosion rates at the ends of the wall.

Gabions: These metal cages filled with rocks are stacked to form other structures (i.e., seawalls, revetments, gabions) and are one of the poorest choices for such construction on the coast.

Geotextiles: Permeable fabrics which can hold materials while water flows through. Geosynthetic tubes are large tubes consisting of a woven geotextile material filled with a slurry-mix (Fig. 1c). The mix usually includes dredged material (e.g., sand) from the nearby area but can also be a concrete mix

Coastal Erosion Management, Fig. 1 Examples of the coastal erosion management by the use of the protection approach. (a) Breakwaters in Colombia, (b) revetment in Italy, (c) geotextiles in Senegal, and (d) beach nourishment in Spain

or mortar. These tubes are placed in the same manner as seawalls or groins but may be buried as well.

Most of the time, hard defenses are employed because they give immediate and tangible protection, and also they generate a sensation of an apparent solution to the protected populations (*The placebo effect* according to Rangel-Buitrago et al. 2018). The long history of the use of such shore-hardening structures has proven that they are a poor choice for CEM in most cases, and there is an extensive literature on how and why such structures fail (see, for example, Paganelli et al. 2014 for a review of short comings). The greatest short coming is that such structures do little or nothing to eliminate the coastal erosion process. Instead, erosion is increased in front of the structures or is transferred to nearby areas because the sediment supply is blocked. The use of hard structures is based on the protection of economic benefits of a given coastal area. However, it is essential to highlight that economic benefits accruing from protection depend on the

values of the land to be protected. Some advantages of the use of hard protection structures include:

- Prevention of physical damage to property as a result of waves and flooding
- Prevention of loss of [economic] production and income
- Prevention of land loss through erosion
- Prevention of loss of infrastructure (mainly focused on recreational activities)

On the other hand, hard structures generate adverse effects, such as:

- Accelerated bottom erosion in front of the hard structures and downdrift scouring (beach loss)
- Disturbance of sediment supply and beach reduction (beach and habitat loss)
- Restricted public access

- Potential risks for bathers (e.g., generation of rip currents, boating hazards, bottom holes)
- Loss of aesthetic visual effects on the seaside landscape

Perhaps the principal problem with the use of hard structures is that once built, they have fixed the location of the coastline in its position at the time of construction. This is highly problematic because coasts are dynamic landforms which respond to several processes such as rising sea levels and wave climate. Management should allow the shoreline to migrate, both landward or seaward; once “held in place,” the system is in disequilibrium.

Soft Defenses

The term “soft” defenses implies designs that have a less severe impact than hard structures, and they usually consist of coastal features that have been created or reshaped using engineering. While hard protection attempts to stop natural forces such as wave energy and tides, soft defenses attempt to adapt the system and supplement natural processes. Soft techniques include:

Beach nourishment or artificial sand supply: The artificial addition of sediment of suitable quality to a beach area that has a sediment deficit (Fig. 1d). This may be achieved through a direct placement of sands on the beach, through pumping or trickle charging (placing sediments at a single point). Sediment placement can be on the emerged part of the foreshore (“beach nourishment”) or under the water line (“underwater nourishment”). Often construction of artificial dunes accompanies such beach nourishment projects. This approach is most common, but it is expensive, destructive of habitat, requires frequent maintenance, may reduce aesthetics, and can actually increase the rate of beach erosion.

Beach drainage: Beach drainage is achieved by a system of perforated pipes under the beach to pump out water, lowering the water table. This allows water to percolate into the beach during backwash, reducing the seaward movement of sediment. The few documented examples were generally not successful.

Beach scraping: Artificial reprofiling of the beach when sediment losses are not severe enough to warrant the importation of large volumes of sediment. Reprofiling is achieved using existing beach sediment. This is a very short-term approach to combating erosion as the sand is lost in the next big storm.

Sand by-passing: Reactivation of sediment transport processes by pumping sediments that accumulated up-drift of coastal infrastructure and injecting them down-drift to maintain beaches. Although successful, this approach is rarely adopted because of the high costs and needed maintenance of the pumping station system. A variant of sand

by-passing is to place sediment dredged from navigational channels onto adjacent beaches to reactivate sediment supply and transport.

Construction of stable bays: By increasing the length of the coastline, wave energy per unit length of the coast is diluted. While some coastline segments are protected, erosion continues between these hard points leading to the formation of embayments.

Cliff drainage: In order to reduce cliff failure by slumping and land sliding, the pore pressure in the rock or sediment is reduced by piping water out of the cliff or bluff, therefore preventing accumulation of water at weak rock boundaries.

Cliff profiling: Slumping and landsliding of cliff and bluff faces can be reduced by lowering the slope angle to increase cliff stability. The angle at which a cliff becomes stable is a function of rock type, geologic structure, and water content.

Rock pinning: Prevention of slippage in seaward dipping rocks can be achieved by bolting layers together to increase cohesion and stability. This does not prevent wave attack at the cliff base but reduces the threat of mass movement and thus reduces net erosion rates.

All of these soft protection techniques need ongoing and constant monitoring, maintenance, and engineering (Edge et al. 2003). Hence, high costs and capability needs should be considered when such approaches are considered. The implementation of soft defenses represents a significant shift from an action-reaction basis (erosion problem = structure) to the adoption of a more proactive approach.

Land Reclamation/Land Claim

The primary goal of this approach is simple: create new land from areas that were previously below high-tide level. This approach is considered an “aggressive” way to protect the coast to such an extent that it also may be called “advance the line,” “attack the line,” “land reclamation,” or “reclamation fill.” Land fill and reclamation is practiced with the sole objective to gain land area to be used for economic purposes, and its use is particularly prevalent in large urbanized coastal areas where land values are elevated (i.e., Hong Kong).

Most of the time, the land claim approach is employed in deltas or estuaries due to the shelter afforded to economic developments, such as ports, as well as the availability of large areas of flat land, that is accessible from both sea and land (French 1997). Generally, this approach is completed with the enclosing and protection of shore or nearshore areas (e.g., diking/polders), as well as sand filling practices, often using the same techniques used in beach nourishment.

The main advantage of the use of land claim approach is the gain of additional coastal land that can be used for diverse

purposes (i.e., urbanization) and its implementation requires the use of mature soil that is optimal for agricultural production. This approach provides an attractive and valuable source of land in places where increases in the coastal population are projected.

Although the direct gain of land is beneficial, the land claim can generate negative impacts. This approach requires either the enclosure of intertidal habitats by hard defenses or their elevation to be increased above sea level to prevent inundations, thus producing a direct loss of coastal ecosystems. In the same way, hard defenses used to claim land causes erosion and scour of the coast and can hinder and even prevent natural ecosystem adjustments in response to changing factors such as sea level rise. Another disadvantage is related to acidification and pollution of the coastal zone. Acidification is linked to the action of bacteria in new sediments which create sulfuric acid when exposed to air, while pollutants can be introduced through the use of dredged sediments for raising land elevation. The above can be a big issue if the claimed land is to be used for agriculture or when coastal waters are essential for development of fishing activities.

Surge Barriers and Closure Dams

The constructions of structures to prevent extreme water levels penetrating a specific area are large-scale coastal protection projects able to defend rivers, estuaries, and tidal inlets. Closure dams are fixed structures that permanently close off a delta or estuary while surge barriers are gates or movable/fixed obstacles that can be closed to prevent flooding when an extreme water level is expected. Both cases are commonly applied at narrow tidal inlets, where the length of the structure is not required to be so high, and where defenses behind the barrier can be reduced both in height or width.

Closure dams and surge barriers may be beneficial for economic purposes. After construction, both structures can be used to develop trade activities. In the same way, they can provide a flexible approach to maintain most of the natural dynamics while still offering reliable flood protection. In particular cases, these structures allow the additional benefit of enhancing a system's natural capacity to clean itself. This can be achieved by independently opening and closing selected barriers, depending on water movement. Closing barriers improve the ability to drive water out of the system, therefore increasing its mobility and dispersing pollutants.

The main disadvantage of implementation lies in its high costs. To implement such protection, high economic investment is required during the construction, and continuous maintenance needs are high. In the same way, surge barriers and closure dams can generate floods on the landward side of the barrier when water levels are high and, in the case of

movable barriers, if the defense remains closed for an extended period. When a movable barrier is used an extra investment in flood warning systems is required to provide information about closure times. This approach can change the chemical, physical, and biological properties of the coastal system altering the inflow and outflow of water. This may generate alterations to water salinity, temperature, suspended matter, and nutrients affecting ecosystems.

Accommodation

Accommodation includes all approaches for addressing coastal erosion by revising and reorganizing human activities in the coastal zone, or even at the river basin level. This approach allows acceptance of a certain degree of flooding and erosion by construction methods, changing land use, and improving preparedness. The above means a continued usage of land at risk without attempting to prevent the area from being damaged by natural events, and allowing conservation and migration of ecosystems (Fig. 2).

In general terms, the accommodation approaches can be divided into two fronts:

- Technologies that allow physical changes to accommodate increased coastal erosion such as, flood proofing, restoration, and floating agricultural systems.
- Information systems to enhance understanding of coastal erosion risks in order to develop appropriate responses to eliminate or at least, minimize impacts. These include early warning systems, indicators, and mapping/zoning.

Accommodation provides opportunities for inundated land to be used for new purposes and some compensatory economic benefits could be derived from this action. However, considerable costs may be involved in the planning and restructuring of land uses. The necessary expenditure may place significant stress on national budgets, especially in developing countries.

The social and cultural implications of the implementation of the accommodation approach can be significant. A shift in the economic activity of an area can change lifestyles of the coastal inhabitants. Also, this approach may lead to living conditions being less desirable, for example, if properties are subject to occasional flooding, or if problems with sewage disposal occur. Public safety and health may thus be adversely affected by this option.

By answering large-scale coastal erosion challenges through accommodation, the full range of coastal erosion collateral effects can be addressed within a longer-term perspective. This may also reduce the need for specific direct coastal protection measures. However, accommodation must be implemented proactively as it requires advanced planning and the acceptance that some coastal zone values could be lost (IPCC CZMS 1990).

Coastal Erosion Management, Fig. 2 Examples of the coastal erosion management by the use of the accommodation scheme. (a and b) Road and building raised (building code application) in Panama.

(c) Example of mapping/zoning in Colombia. The very low to very high designations are for coastal erosion potential

Building Codes

Building codes for the most part address mitigating the impacts on buildings by wind and flood waters, but a few of the regulations in coastal building codes are related to addressing erosion (Fig. 2a, b). Building code requirements specific to managing erosion (FEMA 2008) include:

- Adequate elevation of the building above the expected flood level plus the addition of wave height (i.e., building raised on stilts so flood water and erosive storm waves and/or surge can pass under the structure without inducing scour).
- Keep ground-level under building open or use breakaway walls to allow passage of flood waters without causing significant structural damage or erosional scour.

- Adequately anchor structures against flood flows so they are not swept away to become battering rams against other structures.
- Locate utilities and septic systems below ground at depths not likely to be reached if erosional scour does occur.

Floating Agricultural Systems

Floating agricultural systems are an adaptation approach to cope with increased or prolonged flooding and erosion. In a more specific way, such systems utilize waterlogged areas over long time periods to produce new soil, food, and at the same time avoid damage from flooding and erosion.

This approach uses a substrate of rotting vegetation that acts as compost for soil creation and crop growth in

waterlogged areas. The vegetation floats on the surface of the water, thus creating new spaces for agricultural purposes. Floating agricultural systems mitigate flooding erosion because plant roots create new soil and alter soil properties (i.e., aggregate stability, improve hydraulic function, and shear strength). In this way, cultivatable area can be increased, and communities can become more self-sufficient and at the same time control coastal erosion.

Floating agricultural systems are a relatively labor-intensive approach, so they can provide employment opportunities within communities. Such systems may also aid in food security by increasing the land output while supporting poor and landless people. The main disadvantages of this approach are there are very limited areas where such physical systems can be developed (e.g., shoal areas with low wave and current energy), and such systems are limited by climate conditions.

Forecasting and Early Warning Systems

Long-term weather forecasting provides some guidance in focusing on where coastal erosion events may occur in the future. This allows both managers and the public to be warned so that optimal decisions can be taken to reduce the adverse effects. As such, the primary goal of forecasting and early warning systems is to reduce the exposure.

Forecasting systems help anticipate potential events before they occur. They may determine the hazard and risk. The forecasts increase lead-time for the people to prepare and evacuate and help provide a short time for minimal responses to minimize potential erosion damage. The lead-time can range from hours up to a few days, depending on local hydrological and topographical conditions (susceptibility). The forecasting systems estimate expected erosion using data inputs from simulation tools and models (e.g., storm surge models).

In contrast to forecasting systems, the goal of early warning systems is to issue warnings when erosion is imminent or already occurring. Early warning systems need interrelated elements:

- Assessments and knowledge of coastal erosion-related process in the area
- Local hazard monitoring (forecasts) and warning service
- Erosion risk dissemination and communication service
- Community response capabilities

Forecasting and early warning systems go together. Once erosion is forecasted, early warning systems provide the crucial step to communicate the threat. Due to the current climate change scenarios, both are of vital importance and help to manage and minimize the catastrophic effects of coastal erosion. It is important to highlight that forecasting and early warning systems are not a stand-alone response to

minimization of the impacts of coastal erosion. Both must be coupled with emergency planning measures and should also contain an awareness raising element.

As stressed above, forecasting and early warning systems are not sufficient on their own to reduce coastal erosion risk. People's reactions to warnings – their attitude and the nature of their response – have a significant bearing upon the effectiveness of this approach. These systems are only useful when all inhabitants of a coastal area know what the forecasting and system of warning means, what the stages of warning are, and what to do when the warnings are given (Tompkins 2005). The accuracy is a vital point in the implementation of this approach. System inaccuracies might lead to complacency if previous forecasting and warnings were unfounded. Also worthy of note, in the USA, weather reports often state “beach erosion is expected” which usually means the back beach area will be eroded (i.e., bluff, dunes, buildings' footings) and storm surge and overwash are likely (the beach will still be there after the storm – the houses, maybe not).

Natural Indicators

The term indicator can be defined as the ability to measure and describe variables or as a parameter that indicates some characteristic or metric (Carapuço et al. 2016). An “indicator” may be interpreted as a quantitative/qualitative statement or measured/observed parameter that can be used to describe an existing situation and measure changes and trends over time. In the coastal erosion context, an indicator is a selected group of descriptors that express the predisposition of a coastal segment to be affected by coastal erosion, including evidence of past erosional events. In the coastal erosion management context, there are three types of indicators:

Geoindicators: Describe the physical/morphological features of coastal systems and can be grouped into geology (expressing processes and materials – their relative resistance to erosion) and landforms (expressing the coastal type).

Driver-based indicators: Used to assess coastal erosion vulnerability, namely, in large-scale applications involving semi-quantitative coastal indexes (e.g., scaled in classes from 1 to 5 or from very low to very high). These indicators include the parameters driving coastal erosion (i.e., wave characteristics, sea level, wind).

Process-based indicators: These reflect the interaction between coastal erosion driving mechanisms and the coastal morphology. These indicators are obtained through formulations or models that combine the driving variables (e.g., wave height, sea level) and the morphological parameters (e.g., cliff height, lithology). The resulting indicator has a physical meaning, directly related to the coastal erosion hazard.

Indicators are used to evaluate erosion susceptibility of coastal areas through a relatively fast and low-cost approach. And indicators are of practical use in coastal zone planning and management, because they allow a different kind of monitoring in coastal erosion management. However, indicators are not sufficient on their own to reduce coastal erosion but are tools and the selection of the appropriate indicator and associated thresholds is fundamental to obtain optimal coastal erosion hazard estimation.

Mapping/Zoning

Ideally, mapping should be the first step in CEM, because this is the broadest approach to define those coastal areas which are at risk of erosion under specific conditions (Fig. 2c). Coastal zone mapping usually consists of a range of map types from traditional (e.g., topography, land forms) to specific hazards (e.g., FEMA flood maps, storm surge maps, erosion rate maps). Computer modelling combined with other map data bases allows construction of hazard-specific maps (e.g., Puerto Rico's Tsunami Zone maps). With computers, combining various types of coastal hazard maps provide for hybrid maps to express general coastal vulnerability, usually expressed in terms of a graded coastal vulnerability index (CVI). Coastal erosion is always an aspect of this type of mapping, and all of these map types can be applied to CEM. FEMA flood maps have designated "wave velocity zones" which can be taken as erosion zones, especially for coasts of erodible material. Storm surge maps similarly may indicate the reach of erosive waves and overwash/backwash currents. Projected sea-level rise inundation maps show where new vulnerable shorelines will be. In the Pacific, modelling of El Niño flood areas can be mapped. And old maps and air photos provide data bases for mapping historic erosion rates and changes in those rates. The applied goal of all of these maps is risk reduction, but they also support CEM in working to reduce the impact of coastal erosion. Mapping shows the expected extent of the erosion process in a given location, based on various scenarios.

Mapping is usually the basis for zoning, the common management approach for appropriate land use planning, especially in erosion-prone areas. Coastal zoning is the division of areas into zones that can be assigned different purposes and user restrictions, based on the knowledge of the coastal erosion hazard and other restrictions. Coastal zoning allows multiple users to benefit from a coastal area under a broader sustainable management strategy. Coastal zoning schemes can constitute the regulatory and planning framework for CEM and other coastal management issues. As noted by Bapulu and Sinha (2005), mapping creates easily read, rapidly accessible data sets that facilitate the identification and zonation of areas at risk of erosion and also help prioritize mitigation and response efforts.

One of the drawbacks of past mapping is that the conclusions for some hazards, such as coastal erosion, flood levels, and storm surge levels, are based on past records (historic) or models which also use past information (e.g., wave data, storm frequency) and do not have mechanisms for including the changes that are known to be occurring (e.g., sea-level rise, subsidence rates, impacts of land-use changes). Some newer mapping techniques are now including these variables and generating maps that are forward looking, rather than expecting conditions to remain as they were in the past (e.g., AMBUR, Jackson et al. 2012).

Climate change must be a primary consideration in future mapping. The effects of climate change are far more reaching than just the sea-level rise, and many of the coming changes will create new interactions with the dynamic nature of the coast. For example, changes in extreme waves, occurring as a result of climate change, will generate changes in the areas susceptible to erosion. So traditional maps will require periodic updates to reflect the changing risk of erosion and also to update the existing zonation. Maps should have many final users including developers to determine areas at risk of erosion and by insurers to assess premiums in areas where property is at risk. Maps must be integrated with other procedures, such as emergency response planning and town planning before the full benefits can be realized.

Use of Ecosystems

In recent years, an ecosystem-based CEM strategy has been brought into practice as an approach that is more cost-effective, and sustainable, than conventional schemes. This approach is based on the natural environmental influences over processes related to coastal erosion (e.g., sediment capture and energy attenuation) by restoring or creating ecosystems (Fig. 3).

The use of ecosystems for coastal erosion management is an integrated process to conserve and improve ecosystem health that sustains ecosystem services for human well-being. This approach combines two particular actions:

- Develop or maintain ecosystems quality
- Ensure the best way for delivery of different ecosystem services to human well-being

CEM based on habitat diversification can be applied worldwide, particularly in areas that have sufficient space between existing urbanization and the coastline to allow for ecosystem development (for example, in accommodation strategies). Because ecosystems have the natural ability to reduce extreme wave effects (Shepard et al. 2011), their growth can keep pace with sea-level rise through sediment accretion if available (Kirwan et al. 2010).

The use of this approach gives multiple benefits in comparison with common conventional methods of shore hardening.

Coastal Erosion Management, Fig. 3 Examples of coastal erosion management by the use of ecosystems. (a) Coral reefs in Bonaire, (b) mangroves in Ecuador, (c) salt marshes in Holland, and (d) dune vegetation in Holland

These benefits include natural habitat conservation, the creation of recreational spaces, carbon sequestration, improvement of water quality, production of fisheries, and wave attenuation. In fact, many existing coastal ecosystems already provide some degree of protection with no installation cost.

Despite the many advantages, it is essential to highlight limitations in the implementation of ecosystem-based coastal erosion management. Ecosystems demand space to flourish and sometimes require more space than conventional protection approaches. Flexibility in planning is required as ecosystems usually have a recovery capacity after losses (e.g., storm damage), but this recovery is not immediate. In some cases, recovery can be prolonged and can even become lost due to external factors. In the same way, ecosystem development and functionality will depend on the coastal setting, hydrodynamics, human factors, and habitat dimensions, together with the severity of coastal erosion. Some common protective ecosystems with respect to CEM are as follows.

Coral Reefs

These ecosystems have many functions in the coastal erosion management process, but the most important are

sediment generation and energy dissipation (Fig. 3a). The organisms that make up reefs have skeletons composed of calcium carbonate which allows them to build the rigid reef framework and also to produce sediment when broken up by wave activity or bioerosion. So reefs serve a double function in building the wave-resistant ecosystem and generating sediments. Fragmentation and erosion processes (including bioerosion) transform reef structures into biogenic, calcareous sands, able to feed the coast, and maintain its stability. Reef organisms can also contribute to sedimentation through allogenic processes related to mucous secretions. Coral secretions trap suspended particles in the water column, forming aggregates that sink rapidly to the bottom. Secretions by corals can make it the dominant form of suspended organic matter within and around coral reefs (Marshall 1968).

Their shape and structure allow coral reefs to act as barriers that dissipate wave energy, providing a natural submerged breakwater. Their geometry (porosity, surface, tortuosity, roughness, and the overall void matrix), water depth above the reef system (depth of flow), and length in the direction of wave propagation are vital points in the wave energy dissipation process (Gracia et al. 2018).

Corals collaterally generate environmental and socioeconomic benefits. These ecosystems create high-value biodiversity hotspots that also filter waters, positively affecting overall water quality. From a socioeconomic point of view, reefs provide an essential source of food and income for local livelihoods (i.e., fishing and tourist activities) and contain marine organisms with chemical compounds that have a high potential for medical use.

The main disadvantage lies in that protection activities can be complex technologically and politically – mainly when stress sources are found, and significant economic development activities demand to be foregone in order to protect the reefs. Unfortunately, global warming and acidification of sea water are drivers of reef degradation which cannot be managed and eliminated on a local level.

Wetlands (Mangroves and Salt Marshes)

These are land areas saturated with water, seasonally or permanently, such that they take on the characteristics of a distinct ecosystem (Fig. 3b, c). The prime factor that distinguishes wetlands is the characteristic vegetation of aquatic plants adapted to the unique hydric soil conditions. The major coastal wetlands, mangroves, and salt marshes, are termed “the genuine ecosystem engineers” because of the conjunction of their intrinsic properties (width, structure, tree size), their link with other ecosystems, their function as marine nursery grounds, and their ability to contribute to sediment production and reduction of coastal erosion.

Wetlands can significantly reduce the energy of any fluid that is moving through them. The energy power lost when wind and waves pass through roots and branches can range from 15% to 65%, minimizing seabed scour and further sediment movement (Spalding et al. 2014). At the same time, their structure can reduce winds across the surface of the water, reducing the reformation or propagation of waves. In the 2004 Indian Ocean tsunami, some areas fronted by mangrove stands suffered less damage than unvegetated shores. Vegetation structure is essential in determining possible protection during extreme erosive wave events and tsunamis. Of course, this protection capacity also depends on the size and forward speed of the storm, tsunami characteristics, and coast setting. However, it has been determined that wetlands are more efficient at reducing surge levels if the event passes over relatively quickly.

Mangrove and marsh-grass roots help generate and bind new sediments and soils. The above-ground roots slow down the water-flow process, stimulate sediment deposition, and reduce erosion. Sedimentation rates correlate with root density and between 70% and 80% of suspended sediment brought in from coastal waters may be trapped in wetlands (Furukawa et al. 1997).

Wetlands also provide habitat for a diverse range of plant and animal species (breeding and nurseries for fish, birds, shellfish, and mammals) and can release organic matter to the ocean (e.g., mangroves) providing support for marine life. From an economic point of view, they often serve as an essential source of food and resources for livelihoods (e.g., wood, fishing, tourism) for local communities.

Seagrass Meadows

Seagrasses can significantly influence the hydrodynamic environment by reducing flow velocity, dissipating wave energy, and stabilizing sediment. When a wave reaches the ecosystem, a negligible energy reflection and weak wave attenuation by friction are produced. This situation is opposite of what happens with most hard structures, where the same process gives rise to higher energy reflection and wave attenuation by breaking and friction with further loss of sediment. Additionally, meadows can stabilize and maintain sediments in shallow areas. Due to their ability to dampen waves and currents, seagrass canopies can increase sediment deposition, decrease resuspension, and even directly intercept suspended sediment. Also, substances secreted by epiphytes can bind sediment particles to seagrass leaves. In the same way, they can influence the original seafloor bathymetry through the accretion of rhizomes and roots in the sediments, thus exerting new forces over hydrodynamics and sedimentation.

The efficiency of this ecosystem is primarily and firmly based on the density, standing biomass, plant stiffness and incident energy flux (Gracia et al. 2018). Optimal conditions for enhancing coastal erosion defense provided by seagrasses can be reached at shallow waters and low wave energy environments. Like reefs, seagrass ecosystems can create new high-value biodiversity hotspots and also can filter waters, positively affecting overall water quality. Seagrass meadows support commercial fisheries (offering nursery functions for commercial species).

Artificial plantings of mangroves and seagrasses to reestablish existing ecosystems or encourage new growth should be a consideration for any CEM plan. Removal of either of these systems usually leads to an increase in the shoreline rate of erosion. A primary problem in implementing their use is that some coastlines have high levels of recreational or development activities that disturb these ecosystems.

Shellfish Beds, Banks, and Hardgrounds

A shellfish community or single shellfish species can create shell banks or beds on the sea floor that produce sediment as well as offering a wave-energy dissipating effect. Like reef skeletal material, most shells are calcium carbonate and produce sediment when fragmented. Some, like serpulid worms (polychaetes), are encrusters and bind sediment or may build small reef-like structures. If organisms have a cement

binding, they produce a hardground that is resistant to erosion. These ecosystems are topographically rough, with fractal complexity capable of reducing wave energy and erosion (Commuto and Rusignuolo 2000). Their structures can act as barriers that generate dams, to hold pools of water, and increase immersion time above the shoreward bank margin, facilitating sediment deposition. Extensive shellfish banks and beds can minimize the impacts of direct water flow, extreme waves, storm surges, and can stabilize the shoreline. Under low-to-moderate flow action, increased deposition on beds causes sediment to build up to form banks that can be higher than the ambient substrate.

Shellfish beds or banks implementation has several collateral positive effects:

- Can provide habitat for other species by creating a hard substrate with high surface complexity, acting as attachment sites for sessile organisms and refuges for mobile microorganisms, supporting high levels of species diversity.
- Can accrete dead shell material such that the bank grows in size and mass over time (except where restricted by tidal exposure or when harvested) with decay occurring at varying rates.
- Can provide food for other organisms, either when consumed directly or through the species assemblages they support.
- Can filter the water and reduce turbidity by extracting phytoplankton and organic and inorganic particles from the water column.
- Carbonate shells accumulate carbon in the calcium carbonate of their shells that help reduce the concentration of greenhouse gasses.

Dune Vegetation

Natural dunes offer both a protective barrier during storms and an obvious sand supply for natural nourishment of adjacent beaches (Fig. 3d). Some management schemes include bulldozing sand dikes or ridges under the guise of “dunes,” but true dunes are a complex ecosystem that relies heavily on vegetation and a soil biota. Dune vegetation stimulates dune growth by trapping and stabilizing wind-moving sand. Small plants located on the face of eroded dunes can enhance the natural development above the limit of direct wind or wave attack. These coastal ecosystems need conservation in any CEM plan. Dunes are extremely sensitive to foot traffic and should be protected by such means as constructed walk overs, or limited access paths.

Dune vegetation can be transplanted to encourage the growth of new foredunes along the toe of existing dunes, as long as these species are tolerant to occasional seawater inundation. Planting vegetation from seed can be undertaken but will not usually be successful in the dynamic foredune environment. Transplanted

grasses also need fertilization to encourage the associated soil biota (e.g., Vesicular-Arbuscular Mycorrhizal Fungi).

Vegetation sowing and transplanting per se will not construct new dunes or completely prevent erosion. Plants encourage natural recovery by creating a reservoir of sand within the dunes that better enable their ability to withstand erosion. Fencing, thatching, and beach recycling are often necessary to help in sand accretion. Additionally, these works can provide extra protection from waves and will reduce damage due to trampling. Once vegetation is well established, dunes may become self-sustaining, although any erosion damage will need to be quickly repaired.

The use of dune vegetation can decrease adverse effects on landscapes (even artificial dunes). In the same way, developing a dune system can restore a degree of the natural character to places that once had natural dune complexes before development and provide a valuable coastal habitat for animals. From an economic point of view, dunes help to reach multiple management objectives, such as public access to recreational resources and hazard mitigation.

Transplanting and management of appropriate dune vegetation will have no damaging impact on the natural environment of the receiving area but can be harmful to the borrow area, particularly when sand is bulldozed off of the beach. Over-harvesting of transplants from any region can give rise to increased erosion in specific points. This may be most significant for salt-tolerant sand-couch vegetation, as the borrow area will necessarily be a foredune susceptible to wave over-washing and wind erosion. Also, the use of dune vegetation in coastal erosion management typically requires dune fencing or thatching to achieve success. The construction of fences or thatching will disrupt public use of the coast, so provision must be made for controlled access.

Managed/Planned Retreat

Managed/planned retreat has the primary objective of reducing population, property, and infrastructure at risk through the planned withdrawal from coastal hazard zones, including erosion-prone areas (see “► [Managed Retreat](#)” in this volume). Specific to the erosion hazard, managed retreat implements mitigation tools designed to move existing and proposed development out of the path of both short- and long-term coastal erosion (Fig. 4). The approach may include managed realignment where shore-protection structures are removed selectively to allow natural coastal environments to be reestablished. This coastal erosion management approach is based on a simple philosophy: get out, avoid damage, and recognize that the coastal zone dynamics should dictate the type of management employed.

This approach works well in large areas where retreat strategies allow coastal ecosystems (e.g., wetlands) to adjust to increased levels of the sea through a slow landward migration. On the other hand, in small areas (e.g., islands), retreat

Coastal Erosion Management,
Fig. 4 Example of a new habitat construction (dunes) after moving the existing line of defense in Holland

does not offer a suitable alternative. There may be little or no land for resettlement and also many ecosystems, heritage, and cultural assets that will be affected or could be lost entirely.

Managed/planned retreat raises significant transboundary implications. The institutional capability to conduct a retreat on a temporary or permanent basis must be established. Currently, managed/planned retreat is supported under practices and legal tools that allow moving property and people out of coastal zones affected by erosion.

Management Realignment

Managed realignment is the process of moving back existing defenses in a coastline allowing the reestablishment or creation of a new intertidal habitat area through its natural regenerative capacity or reclaimed land (Fig. 4). This intertidal habitat will be highly effective at attenuating wave energy and also will reduce offshore sediment transport and therefore erosion. Intertidal habitats also can form dense root mats which increase the stability of intertidal sediments, helping to mitigate coastal erosion (USACE 1989).

This approach involves well thought out plans for the retreat of communities and ecosystems with a landward shift of the ecosystems. It is appropriate in areas where low-cost agricultural land holds sway, where there are few structures or directly affected stakeholders, and costs of compensating owners are minimized.

Managed realignment can be implemented following four methodologies:

Removal: Defenses are removed allowing the coastline to respond more naturally to hydrodynamic process.

Breaching: Selected existing defenses are removed to allow tides and waves into the previously protected land.

Realignment: Change in the position of the line of defense to favor the development of a more dynamic coastline.

Controlled tidal restoration: Tidal flow into the embanked area is controlled while defenses are maintained.

The main disadvantage of the managed realignment is the loss of private properties and commercial income. This approach is not politically and economically viable in urban areas or where agricultural land is of high quality.

Avoidance

Avoidance is ensuring that new infrastructure and assets are not permitted in areas likely to be affected by coastal erosion, without substantial planning controls being implemented. Avoidance may not seem like a managed retreat, but defining areas where no development is allowed because of coastal erosion, strategic ecosystems, or limited sediment sources should be part of any managed retreat plan. This approach can be developed in four specific ways:

Setbacks – hold the line: A coastal setback can be defined as the distance to keep structures out of coastal erosion or at least at a reasonable distance from a hazardous process. The idea of a coastal setback is simple: to allow room for the high water mark to naturally move inland throughout all the service life of the property. This approach enables erosion to continue along specific sections of the coast, while further development is not authorized or at least restricted. Setbacks can be divided into two types:

- **Fixed:** Limits growth for a set distance landward from a specific reference feature.
- **Rolling:** The regulatory line shifts landward according to topography or shoreline movement (dynamic or natural processes are used to lay out the setback line).

The adoption of arbitrary distances which do not indeed represent the threat from erosion can generate problems; in that sense, setbacks should be established based on real information (i.e., shoreline evolution or extreme water levels).

Rolling easements: This legally enforceable expectation is that the shore or human access along the shore can migrate inland instead of being squeezed between eroding coasts and a fixed property line or physical structure (Titus 2011). In a more specific way, it is a legal instrument that allows publically owned land, and land use restrictions, to migrate inland as shorelines retreat.

Rolling easements, like coastal setbacks, are measured against a coastal benchmark (e.g., high water line, dune crest or vegetated area). Because these benchmarks are expected to move dynamically with changing coastal conditions, the easement is said to “roll.”

A rolling easement can work in two ways:

- As a regulation that prohibits shore protection.
- As a property right to ensure that an area moves inland with the natural retreat of the shore.

Although the regulatory approach is the more common way to prevent shore protection, the nonregulatory approach may sometimes work better. Private land trusts, government agencies, and (for some plans) even private citizens can buy (or secure donations of) rolling easements from property owners. An owner who has voluntarily engaged in the creation of the rolling easement is more likely to perceive the arrangement as fair than a landowner subjected to government regulation.

No-build/No dwelling zones: These are areas, defined under laws and policies, that are not recommended, or are forbidden for human habitation and infrastructure development because of a high degree of coastal erosion susceptibility. The basis of this approach lies in the conservation of an eroding shoreline which is more than just a buffer zone and usually is a state policy to uphold the people’s constitutional right to life and property.

Construction disincentives: Legal strategies to encourage people not to build in high-risk zones or areas of critical habitat. This approach is based on the premise that construction over regions with high erosion rates cannot be covered for insurance or any federal assistance (i.e., small business loans and funding to rebuild infrastructure).

Acquisition

Land acquisition is the process wherein coastal lands are acquired by the government to protect them from future

coastal erosion related problems. This acquisition can be made through negotiated agreements where owners voluntarily sell the property, or, in extreme cases using compulsory purchase.

In some nations, the acquisition approach is developed through a legal figure called “coastal public reserves.” It consists in the designation of a strip of land measured from the high water mark and running along the shoreline as land owned by the state. This approach provides benefits concerning conservation, providing public access to the shore, contributing to recreational and tourism needs, preserving aesthetics, and protecting habitat.

Relocation/Resettlement

This is the process of one person or a community leaving an area affected by coastal erosion. The approach can be developed in three different ways:

Active: Undertaken by moving a building back either before it is threatened, or, if threatened, before it is damaged.

Passive: Rebuilding a destroyed structure in another area, away from the shore, and out of the coastal hazard zone.

Long-term: Implies a broader strategy through community zoning or land use plans that identify a frontal zone of buildings likely to be affected by known erosion rates.

Although relocation may represent the most effective long-term adaptation strategy for some coastal communities, this option is still considered outside the range of acceptable possibilities due to political, institutional, sociocultural, and economic considerations. Also, the “where” and “when” to relocate has not always been clear or adequately enforced.

Sacrifice/Abandonment

The sacrifice approach allows property loss when other suggested protection measures are not viable, or the accommodation and retreat option does not exist (Fig. 5). Sacrifice may be viewed as an “extreme” strategy, because it is frequently recommended after extreme-erosion events leave buildings battered and broken (Fig. 5). Yet abandonment is usually the safest and most economic, because it avoids reconstruction in the hazard zone and the repeated losses that follow. This planning strategy can be developed in four ways:

- As a “do nothing” approach in which buildings are regarded as having a fixed lifespan, and when their time comes to fall into the sea, no attempt is made to protect them.
- As an emergency program that encourages relocation of buildings before a hazard event to avoid economic loss.
- As a law that bans post-erosion reconstruction or by requiring relocation landward of the revised post-erosion setback control line.

Coastal Erosion Management, Fig. 5 Examples of sacrifice/abandonment approach in (a) Colombia and (b) Brazil

- As denial of insurance and subsidy programs in order to discourage rebuilding actions after erosion.

According to (Williams et al. 2018), the minimum needs to develop a sacrifice practice in a coastal area are:

- Identify the rationale behind the decision.
- Use demonstration sites to present the feasibility of accommodating retreat.
- Assess the geomorphological/ecological changes and indicate the advantages of allowing them to occur.

Summary

In the twenty-first century, the wise implementation of coastal erosion management is facing a challenging set of global changes: an increasing population in the coastal zone, the parallel increase in property development, the on-going sea-level rise, increasing the reach of erosional processes, potential increasing storminess (wave energy, storm, surge, rainfall runoff), and the unsustainability of traditional antierosion projects (e.g., increasing costs for hard and soft approaches, and decreasing sand supplies for nourishment). Past coastal erosion management has not been particularly successful, primarily because social-political systems are more driven by the profit motive than by utilizing the knowledge base

and tools to avoid and/or mitigate erosion. The time has arrived to do more than just implementing one or a combination of the previously presented approaches. Improving CEM requires policies and implementation processes involving more in-depth knowledge of the processes implicated in coastal erosion and optimal strategies and operative management frameworks. The basis should be based on historical and scientific knowledge in order to come to solutions that fit CEM frameworks and should be carried out following the best available techniques. Clearly, some traditional strategies must be abandoned and current underutilized approaches given more consideration in addressing erosion problems (e.g., use of ecosystems, managed retreat).

CEM is not about just solving a problem by the use of one of the five approaches presented in this entry but rather about future livability with the coastal environment. CEM must be the critical point, together with the ongoing process, that demands a constant identification of risks and opportunities, implementation of coastal erosion reduction measures, and especially the review of strategy effectiveness. The optimal performance of any strategy must be carefully monitored and assessed and results feedback through the entire cycle to improve use and future interventions.

Strategic planning for CEM relies on understanding the processes responsible for shaping coastal morphology. This process not only needs to include the local or regional procedures, but also the inclusion of the processes that lead to the formation (even the physical and chemical weathering) and the physical sediment supply that are of importance for the coast. Likewise, such strategies must be developed within policy frameworks that set clear objectives, and in an institutional environment where stakeholders have different defined roles.

CEM can be a slow process, so expected results are likely to be met in the medium- to long-term time frame. In this sense being proactive is the crucial issue. Flexible strategies instead of reactive measures should be adopted to strengthen CEM and thus improve the coastal environmental quality. A considerable level of cooperation is required from all stakeholders to take actions using CEM. This will help foster and close existing links between CEM, disaster risk reduction, and climate change adaptation, as well as between science and policy.

Coastal Evolution in Microtidal Seas in Holocene

Kazimierz Furmańczyk

Institute of Marine and Coastal Sciences,
University of Szczecin, Szczecin, Poland

Introduction: Origin of Coasts and Their Main Evolution Factors

A general layout of the shoreline depends on land and bottom surface and the sea level. Both the Earth's crust and water volume undergo continuous and slow balance changes which affects the coastal zone landscape. Coast evolution rate depends on several factors as described by Cooper (1994), including geological, geomorphological and tectonic settings, paleotopography, climate, sea level changes, wave energy (wind), volume and direction of sediment supplied by river load, and intensity of coastal processes.

It would difficult to determine the impact of all the factors everywhere on the Earth. Therefore, the southern coast of the Baltic Sea was selected as a specific laboratory, where the magnitude and intensity of certain factors influencing the development of the coast can be limited. Such approach facilitates understanding of coast evolution processes.

An area extending from Scandinavia to the Baltic Sea basin was covered by an ice sheet in the past. The glacier had transported and then deposited moraine material (till, sand, xenoliths, boulders) its retreat creating a specific surface topography in the Southern Baltic area.

Moraine uplands of mainly undulating relief, that may be locally planar or hilly, are predominant. In turn, plain relief is attributable to remains of former ice-dammed lakes, bottoms of ice-marginal valleys that used to transport the meltwater and areas of marine accumulation plains.

The coastal evolution in the southern Baltic Sea in the Holocene was proceeding in the past and is proceeding now under the influence of: eustatic sea level change and glacio-isostatic adjustment (GiA). (Harff et al. 2017).

Ca. 8 ky BP sea level of the Baltic Sea was approximately 20 m lower than at present (Fig. 1). Where the coast and the land meet, the so-called coastal processes take place and modify the coast. The evolution rate of the coast depends mainly on its geological structure. The southern Baltic, coast is composed of sand and till originated during the Holocene deglaciation (sedimentation) in the temperate climate zone and in the nontidal sea environment.

Several factors and their intensities have been affecting the development of the Baltic Sea coast since the Holocene, among which the sea level rise and its fluctuations (Fig. 1) along with wave action have been playing key roles.

Sea level fluctuations trigger a displacement of the main zones of wave energy dissipation and the hydrodynamic zones related to them. Eustatic sea level fluctuations, which are associated with climatic changes, and neotectonics within the coast (uplift or subsidence of the basement), which induces the so-called “relative sea level fluctuations with growing trend,” are crucial in a particular timeframe (Harff et al. 2017).

Coastal Evolution in Microtidal Seas in Holocene, Fig. 1 Relative sea level changes of the southern Baltic in Late Pleistocene and Holocene. (Modified after Rotnicki 1995)

Within the southern Baltic, “pulsing and oscillating” sea level fluctuations occurred during the Holocene transgression. Apart from the continuous sea level rise, the transgression was slowed down a few times and even short-term regressions were demonstrated to have happened (Rotnicki 1995). These fluctuations took several hundred years and ranged within a few meters (Andrén et al. 2011; Uścińowicz 2014).

In the Late Holocene, during the Subboreal (6–5 ky BP) the marine transgression started to grow weaker (because the ice shield’s cooling effect changed) and the mean sea level rise rate dropped to ca. 2 mm/year. The southern Baltic shoreline got close to its a present configuration, while the sea level was 2.5–3 m lower than now. During the Subboreal and Subatlantic (i.e., within the last 5 ky), the shoreline was getting slowly closer to its present configuration.

The sea level rise rate has been a very important factor in shaping the coast profile. Long-term sea level fluctuations, i.e., the sea level rise and decline, result in shore erosion or accumulation, respectively.

Origin and Migration of the Southern Baltic Sea Barriers

Ca. 80% of the southern Baltic coast is composed of barrier and/or spit-type shores which include extensive dune systems a few up to 40 m high (Fig. 2). They developed on low-lying

Coastal Evolution in Microtidal Seas in Holocene, Fig. 2 Some peninsula, spits, and barriers of the southern Baltic Sea coast (Furmańczyk and Musielak 2015, supplemented)

sections of the coast, mainly in places where ice-marginal valleys and coastal lowlands reached the sea.

The dune-covered sections of the coast feature different dune morphologies. They are mostly represented by one or a few berms running parallel to the shore. These forms separate the sea from: ice-marginal valleys, wetlands, and coastal lakes. Dunes cover postglacial moraine deposits (sand and till) along some section of the coast.

As a result of long-term impact of the sea on the shore, its outline is generally levelled out and feature dominant barrier landforms that are specific for the fluctuating nature of the sea level rise in the Holocene (Furmańczyk and Musielak 2015).

During earlier phases of the southern Baltic Holocene transgression (8 ky BP), shore destruction was very intense, whereas during later phases (since 6 ky BP), when the shore erosion was much weaker, the transgressing sea water moved inland to shape the coastal zone landscape (Mörner 1980; Rosa 1984; Rotnicki 1995; Uścińowicz 2003). Storm-driven waves undercut the moraine uplands causing their retreat and leading to the formation of cliffs. Depending on wind direction and sea level changes, sandy sediments produced by erosion were supplying the beaches (in front of cliffs and on their both edges) and the submerged part of the coastal zone. Subsequently, those sediments were carried away along the shore or into deeper parts of the nearshore zone.

Simultaneously, waves, that were affecting gentle slopes of valleys, produced wide beaches and underwater bars parallel to the shore. As the sea level was rising, these were gradually moving inland. During periodical episodes of sea level decline the bars emerged above the sea surface, the shore featuring a wide beach. The beach became a source of wind-transported sediments building the dunes. At that time barrier dunes, the height of which depended on the volume of sand material available, were formed. The underwater bars, mentioned above emerged and formed barrier islands.

Ca. 4.5 ky BP, there was a longer period of evident sea level stabilization, and even a decline (Fig. 1). Throughout that period, aeolian processes were intense within the area of wide beaches and emergent bars to produce rows of sandy barriers in the form of dune berms parallel to the shoreline. The next sea level rise, that was not as rapid, resulted in a gradual migration of these barriers toward the land (Figs. 3 and 4). Similar phenomenon was observed on the Atlantic coast of US (Leatherman 1988).

Sea level fluctuations in the coastal zone are of different origin, amplitude, and duration, while their impact on the coastal zone differs also spatially. The sea level rise rate has an essential impact on a way the spit/barrier coast is reconstructed. Tillmann (2015) developed a similar rollover model for the German North Sea coast.

Simultaneously, the former land areas transformed into present-day spits, experienced a rise of a groundwater table due to the sea level rise; increased water content of coastal lowlands was conducive to the development of peatbogs, as well as for the growth of bushes, trees and even forests. Coastal lakes emerged every time the groundwater table rise was faster than the peat-forming process. Some of those lakes were being filled up by dune sands from barriers that were migrating due to the sea level rise (Fig. 5).

Those barriers that were moving further inland might have cut off parts of sea bays. When the sea level rise rate was faster than that of the dune berm rise produced by aeolian processes, the barriers were disrupted and inlets linking coastal lakes with the sea or flood deltas were formed as a result (Rosa 1984).

The functioning of moving barrier systems should be associated with the origin and gradual development of all the large accumulation landforms of the southern Baltic coasts. It was the sea level fluctuations modified by the vertical Earth crust movement (uplifting and subsiding) that were deciding on the development of both cliff and dune coasts (Furmańczyk and Musielak 2015).

The moving barrier effect mentioned above occurred in the Łeba Barrier area. A dune berm was formed there during the sea level fall that lasted several hundred years. During another episode of the sea level rise, the barrier moved inland landwards across a several hundred year-old forest. Nowadays, tree trunks are periodically unearthed on the beach and in the shallow nearshore bottom after storms (Fig. 4).

In many places along the coastal barriers where peat had been forming, there were separated swamps or shallow lakes. As the sea level was rising and the land was subsiding, a further transgression of barriers resulted in their gradual encroaching the peatbogs or coastal lakes. At the same time, erosion affecting the seafront side of the dune berm (rollover and barrier translation), the beach, and the seabed revealed peat outcrops at different depths within the nearshore zone (Fig. 5). This effect can be seen on aerial photographs of

Coastal Evolution in Microtidal Seas in Holocene, Fig. 3 A sketch of dune barrier migration along with the sea level rise

the coastal zone off the Dziwnów Spit near Międzywodzie (Fig. 6). Peat deposit outcrops are visible as dark patches, the bright areas being sands covering the peat. Peat outcrops occur at a depth of 1.5–2.0 m.

The barriers, at both ends, contact hills of moraine uplands or front moraines, the sand, and till slopes of which are being eroded by the sea. The material eroded this way migrates along the shore and nourishes the adjacent barriers. It is transported by waves and currents that depend on wind force and direction. The barrier size and thickness at sites of dune formation depend on the amount of sand material released by the erosion of the nearshore seabed or adjacent cliffs.

Present Responses of the Coast to Sea Level Fluctuations

The barrier coasts and peninsulas at the southern Baltic coast were evolving throughout the Holocene and the evolution has not terminated yet. The evolution produced all the sandy spits of the southern Baltic Sea (Fig. 2), including the largest. Sediment transport perpendicular to the shore, controlled by

Coastal Evolution in Microtidal Seas in Holocene, Fig. 4 Tree trunks revealed after the storm event on the beach of Łeba Barrier. Some trunks stand in situ, while the rest migrate along the shore (Mielczarski et al. 1990). (Taken from www.polskaniezwykla.pl) Photo: Jacek Meller

sea level fluctuations was a dominant factor in their formation, while the longshore transport resulted in their evolution.

The wind-generated waves markedly affect the seabed and the shore, transmitting a high amount of energy within certain spatial ranges and periods of time. As shown by field experiments, both wave parameters and water level changes at the shore, are crucial for morphodynamic effects of energy dissipation (erosion, accumulation). This concerns the entire spectrum of sea level fluctuations occurring in the nearshore zone, including storm surges, baric waves, infragravity waves, seiches, etc.

When the sea level is low, waves of higher parameters rebuild the seabed and drive the sediment transport perpendicular to the shore in the so-called “dynamic seabed layer” (Deng et al. 2014).

The rising sea level drives the wave energy dissipation zone inland, while the swash may reach the cliff foot or the dune base, triggering its erosion.

Erosion of a coast and the seabed affected by river inflow is the main source of sediment in the coastal zone. The material delivered this way moves along the coast or perpendicular to the shoreline depending on a resultant direction of the transporting factor (wind, waves, currents) and the underwater slope. As shown by results of long-term experiments and theoretical studies, the processes directed perpendicular to the shoreline are more diverse than those directed parallel to it. This is because the water velocity and sediment transport intensity are affected by complex and pronounced temporal and spatial changes in the short and long term. The following coastal forms are formed or transformed as a result of cross-shore transport: underwater bars, shore berms, beaches and, with an input of aeolian transport, coastal dune berms. If the direction of the transporting factor is oblique to the shore, a longshore sediment transport is triggered, its direction depending on the angle of approaching waves.

In the southern Baltic, sea level rise records have been maintained since 1811. The record series is shown in Fig. 7.

The process is modified by the North Atlantic Oscillation, which controls North Sea inflows to the Baltic.

The inflows are responsible for local periodical sea level rise in the southern Baltic. The sea level may rise by up to 1 m, the elevated level remaining for a couple of days or even weeks. It was also possible to identify periods of time (A) with the sea level fall of a few centimeters which usually takes

Coastal Evolution in Microtidal Seas in Holocene, Fig. 5 A sketch of peat outcrop origin

Coastal Evolution in Microtidal Seas in Holocene, Fig. 6

Coastal Evolution in Microtidal Seas in Holocene, Fig. 7

Graph of mean annual, 11 years moving average and linear trend, sea level fluctuation at Świnoujście between 1811 and 2006, divided on potential phases of erosion (E) and accumulation (A). (Musielak et al. 2017). Arrows mark the maxima and minima 11 years moving average within phases of erosion and accumulation

about 10 years. Even such slight falls resulted in a greater shoreline stability and even widening of the beach, sand accumulation within the foredune (also in front of the cliff), and in raising of the dune berm (Fig. 8).

Periods of time (E) which are basically longer than periods (A), are characterized by a rise of the mean sea level, which produces mainly narrowing of the beach and even its complete disappearance after storms. The foredunes, dune berm, and cliff foot are also damaged then. The periods (A) mean sea level stabilization or even a fall as well as an increase in the barrier dune volume or dune accumulation at the cliff foot.

Shore exposure to main directions of incoming waves (including the shadow cast by islands) and wave fetch length are of significant importance for the evolution of the coast. Other important factors include: locally differing rates of the

Earth crust vertical movement and the vulnerability to storm surge of a shore due to its specific location in a bay or a basin protected by a group of islands, as observed in the southwestern Baltic Sea. In addition, direction and passage velocity of cyclonic systems (low-pressure systems) which produce water swell (especially in bays) and control the direction of wind and waves affect the coast as well.

On a time scale of hundreds and thousands of years, all those factors were changing in line with climate changes. Hence, the coast evolution trends present in the past were changing too. Therefore, the magnitude and direction of changes observed along the southern Baltic coast cannot be treated as uniform (Musielak et al. 2017).

Adverse hydrological and meteorological conditions (strong waves, storm surge) coupled with the sea level rise,

Coastal Evolution in Microtidal Seas in Holocene, Fig. 8

A sketch of morphological results decades sea level changes: rising up – erosion (E) and riding down – accumulation (A). Without impact of vertical Earth crust movement

may result in extreme effects leading to catastrophic changes in the coastal zone, including dune breaking and lowland flooding (storm flood); they may also trigger cliff erosion, thus posing a hazard to the infrastructure located in the vicinity. On a time scale of tens of years, they occur irregularly.

Conclusions

Factors and processes that decide on evolution of shores made of sand or sand and till are very complex. The most important of those factors and processes are:

- Geological structure, tectonics, and vertical movement of the Earth's crust
- The progressing sea level rise and its periodical fluctuations
- Location-specific conditions such as sheltering by islands, shoreline azimuth, situation in an embayment, etc.
- Hydrological and meteorological conditions such as the dominant parameters of wind, waves, etc.

All these factors and processes influence the evolution of the southern Baltic coast. In tidal seas the factors will be slightly different, with a much higher of wave energy, and the presence of permanent longshore currents.

Definition

Coastal flood hazard mapping (CoFHaM) is a tool used to determine flood zone limits inland and in other areas exposed to coastal floods due to different hazards such as storm, surge waves, sea level rise caused by climate change, inland storm surge, heavy rainfall, among others. Its areas are identified through maps made by one or more researchers using the Geographic Information System (GIS) software. Generally, its maps display particular levels of flood hazards and risks, with different parameters defined as low, medium, and high.

Introduction

Floods are among Earth's most common and most destructive natural hazards (Nadeem et al. 2014; Gigović et al. 2017; Udin et al. 2018 p. 47). Most of these large floods occur in territories near the coast. The coastline represents an attractive zone for the establishment of various economic activities (IPCC 2007; Halpern et al. 2008). This singular space, over centuries, has been valued and has received high anthropic activity as well. The everyday presence of densely populated urban settlements located on the beachfront, raises concern in the scientific community, due to the different vulnerabilities

and risks these communities endure. Coastal communities are increasingly experiencing climate change – induced coastal disasters and chronic flooding (Lipiec et al. 2018). These relevant coastal problems have led to the development of sophisticated coastal flood hazard mapping (CoFHaM) techniques in recent years.

Coastal flood hazard mapping (CoFHaM) has evolved over time. The first maps only presented static models of historic flood extensions as a guide for planners (Coller et al. 2018). In recent decades, coastal flood hazard mapping has been perfected with the introduction of computer modeling and mapping. These contemporary techniques offer a much greater power of cartographic representation, and they permit experts to evaluate a variety of possible events of floods in numerous places (Coller et al. 2018). The development achieved by the digital mapping of coastal flooding and the wide variety of models available today, which are generated through the use of computer systems, has also replaced the traditional use of paper maps. CoFHaM tools have also been perfected and diversified through the use and facilities provided by web mapping. Some of these websites are accessible and allow their users to share information about flood hazards (Coller et al. 2018). Examples of this service are provided by the environmental agency for the flood map service of England (Environment Agency 2013) and the National Flood Insurance Program (NFIP) in the U.S. Consumers can visit www.FloodSmart.gov to learn how to prepare for a flood, how to purchase a National Flood Insurance Policy, and how to access the benefits of protecting your home and property from flooding.

Coastal flood hazard mapping (CoFHaM) also originates as an instrument for territorial planning which, in a preventive way, guides urban planners and government officials in general. Furthermore, it helps them in the decision-making process when dictating insurance premiums which ideally reflect the way this risk is overseen. CoFHaM makes it possible to prepare answers in advance when facing emergency situations in areas where engineering protection is not practical. CoFHaM has begun to play an important role in raising public awareness of flood hazards (Coller et al. 2018).

Coastal flood hazard mapping tools are essential in flood risk assessment, as well as land use planning, supporting engineering decisions concerning flood control measures, and coordinating emergency responses (Coller et al. 2018). Modeling inland storm surge flooding is also a fundamental step in flood hazard mapping. As the primary tool for communicating flood exposure, flood maps quantify the spatial variation of flood effects (Hatzikyriakou and Ning 2017).

CoFHaM is used for a variety of potential situations such as hazard mapping impacts, vulnerabilities, and risks by means of land, air, and water, e.g., for structural vulnerability estimation (Hatzikyriakou and Lin 2017), flood risk analysis (FEMA 2017), and for offshore wind resource forecast. They

are also used to broaden the understanding of diurnal coastal flows, to improve models for offshore wind power (Colle et al. 2016), and to assess flooding potentialities in rivers located in large areas (Speckhann et al. 2018). Furthermore, CoFHaM is used to simulate storm surge waves, coastal flooding (AMA 2014 a, b; FEMA 2003a) and tsunami hazards (Priest et al. 2018); to map habitats and develop baselines in offshore marine reserves (Lawrence et al. 2015); and to undertake the mapping of the areas protected by Levee Systems (FEMA 2003b), as well as the urban coastal area (Gigović et al. 2017) and the coastal radiological hazards (Martin et al. 2018) among others.

Some researchers have undertaken some important theoretical discussions about flood hazard mapping in coastal zones. There are authors and institutions which analyze different scenarios and coastal limits where there is an incidence or direct impact of the sea towards the land surface, e.g., storm surge waves or sea level rise (FEMA 2003a; Hatzikyriakou and Ning 2017). Other scientists analyze the flood hazard mapping considering the river basin as a determining part of the coastal environment (Udin et al. 2018; Speckhann et al. 2018; Milanés et al. 2017, FEMA 2009). This second position is considered a holistic one, because it integrates two flood hazard scenarios: (1) *the danger produced inland due to floods of rivers during their outfall into the sea and the combination of this scenario and the impact on its coastal limits after sea-flooding* (see Fig. 1) and (2) *the danger coastal floods produce on land due to sea-flooding or storm surge, as a result of a tropical storm, a hurricane of a different category or the gradual rise in sea level due to climate change* (see Fig. 2).

In Figs. 1 and 2, by using CoFHaM, a digital flood hazard database was created by compiling the best available data on flood-hazard areas and coastal risks; a systematic method to integrate coastal and riverine flood hazard areas was considered. In this case, coastal flood hazard boundary in land use planning was incorporated into the digital flood hazard database. Also, a combination of housing census data alongside the digital flood hazard database, using the geographic information system, satellite imagery, and digital photographs, was also employed.

The definition of coastal boundaries by nature of hazard is significant in the preparation of flood maps (Milanés 2018 a, b). Generally, each floodplain or flood hazard area is divided into flood insurance rates which are based on the floodplain boundaries determined on a work map (FEMA 2015, p. 1). Floodplain boundaries are delineated on the best available topographic mapping using the water-surface elevations determined at cross sections. Between cross sections, water surface elevations in riverine analyses are interpolated (FEMA 2015, p. 4).

In this entry, a critical review concerning different methods for coastal flood hazard mapping designed by relevant authors were shown. The materials, methods, and scales used are also described. Finally, two case studies using several methods and areas exposed to different coastal flood hazards in south-eastern Cuba are presented. In both case studies, coastal populations are exposed to different vulnerabilities and risks.

Methods and Tools Used for Coastal Flood Hazard Mapping (CoFHaM)

Each country determines the institutions which are responsible for centralizing risk maps. In the USA, flood mapping dictating insurance premiums which ideally reflect this risk is governed by the Federal Emergency Management Agency (FEMA) through its National Flood Insurance Program (NFIP) (Hatzikyriakou and Ning 2017; Crowell et al. 2007). FEMA prepares flood hazard mapping to create broad-based awareness of flood risk, provide data necessary for mitigation programs, and rate flood insurance for specific properties (FEMA 2015, p. 1). In Cuba, several institutions work in CoFHaM development, but the so-called “*Defensa Civil*” (The Cuban equivalent to FEMA) is the governing body which centralizes these studies and makes vital decisions.

Flood hazard mapping can be used for hydrodynamic models (Hatzikyriakou and Ning 2017; Dietrich et al. 2011). Other flood hazard mapping methodologies which combine flow frequency analysis with the height above the nearest drainage (HAND) model are applied in river basins. Its flood hazard mapping methodology, combines flow rate analysis of annual maxima with the HAND model (Speckhann et al. 2018), (see Fig. 3).

There are other tools of coastal flood hazard mapping which incorporate statistical analysis and meteorological modeling. There are others which use frequency curves over a range of potential rainfall and precipitation events (Coller et al. 2018). At times, the frequency analysis is also combined with the spatial modeling of the impact of floods on the curves of basic benefit costs (Morita 2008).

Figure 3 displays six methodological systems used by different authors for coastal flood hazard mapping. These tools were used in rural areas, river basins, coastal municipalities, and urban areas. A great difference is observed in the sequence of steps taken for these methodologies, which vary from three to eight stages according to their depth levels. Depending on the nature of the danger, Cuban methods differ in their ways of mapping floods; e.g., floods due to heavy rain (AMA 2014a) or due to sea floods (AMA 2014b). Other

tools are used to separate the coastal and riverine zones and incorporate this new boundary line into the digital flood hazard database (Crowell et al. 2010).

Gigović et al. (2017) considers six factors which are relevant to the hazard of flooding in urban areas: *height, slope, distance to the sewage network, distance from the water surface, the water table, and land use*. Expert evaluations take into account the nature and severity of the observed criteria; and these are tested using three scenarios: (1) the modalities of the analytical hierarchy process (AHP); (2) the use of the fuzzy technique for the exploitation of uncertainty with the AHP method, and (3) contemplate the use of the traditional AHP method (See Fig. 3).

In order to communicate flood exposure, FEMA developed flood insurance rate maps (FIRMs) which have the purpose of classifying coastal areas into flood zones based on two principal criteria. The first is the area's base flood elevation (BFE), which represents the elevation of the estimated 100-year (i.e., 1% chance annually) flood event. The second criterion is the expected wave conditions associated with this event, specified as a range (e.g., “greater than 3 feet”). Another approach to evaluating FEMA's flood hazard mapping for a location is to compare it with simulated inland flooding from a historical event (Hatzikyriakou and Ning 2017, p. 954).

Material, methods, and scales used for coastal flood hazard mapping are diverse. For the application of coastal flood hazard mapping (CoFHaM) Geographical Information Systems (GIS), historical data on floods, satellite imagery, base flood elevations, wave and tide gage data quadrangle maps showing the location, designation, and elevation of all high-water marks in hard copy and as a GIS spatial data coverage are used. Some hydrologic models, contour mapping or digital elevation models, topographic data, multicriteria decision analysis, assessment of experts, nature and severity of observed criteria can also be considered. The latter are tested using different scenarios or analytic hierarchy process technique as well as satellite photos or digital photographs of each high-water mark, of each coastal infrastructure (such as roads, bridges, culverts, or canals). Other flooding, risk, and vulnerabilities factors are also mapped.

Other methods use aerial photography and on-ground reports from NOAA and/or the media (namely, media reports from source such as the Internet, newspapers, radio, mobile, television, smart phone), information provided by local and state emergency managers, and other federal agencies (i.e., governmental situation reports, mathematical models intended for riverine flood analysis, diagnosis and preliminary damage assessments, experts criteria, preliminary damage assessments for hurricane events, telephone logs and brainstorm among specialists). The final results can be successfully used for spatial city development. The work scales can oscillate from 1:2000 to 1: 25,000 or higher depending on detailed

Coastal Flood Hazard Mapping, Fig. 3 Different methodological schemes for coastal flood hazard mapping

studies. The smaller the scale the higher the levels of detail provided by the map.

On the other hand, the impact of models may change in accordance with and when compared to different models and countries. In the USA, areas within the one-percent-annual-chance (100-year) floodplain boundary are typically termed “Special Flood Hazard Areas,” and areas between the 1% and 0.2% annual chance (500-year) flood plain boundaries are termed areas of “Moderate Flood Hazard” (FEMA 2015) while in Cuba, areas that will be exposed to flooding by 2050 are considered moderate hazards, and areas already exposed since 2010 are in considerable danger.

Cuban Cases Studies

This section illustrates two case studies prepared in accordance with Cuban methodologies proposed by the Environment Agency of Cuba (AMA 2014 a, b). In the first case, flood scenarios are analyzed in the face of coastal hydrometeorological hazards combined with heavy rains, storm surge by category I, III, and V hurricanes, and sea level rise due to climate change from the 2050s up to the 2100 s. For the determination of assets and infrastructure exposed in the Primary Environmental Coastal Units for Integrated Management (PECUIM-Chivirico), located in the province of Santiago de Cuba, a multithreat and vulnerability analysis at a scale of 1:2000 was carried out. The models contemplate the vertical movements of the earth’s crust (*Neotectonics of the Cuban archipelago*).

The modeling of the flood scenario due to heavy rains was carried out following the calculations made by the provincial multidisciplinary group of hazard, vulnerability, and risk studies (CITMA 2013). The MapInfo version 12.0 Geographic Information System was used to obtain the flood areas for category I, III, and V hurricanes to also access the areas of Sea Level Rise due to Climate Change (SLRCC) and to generate all cartographic processing. For the raster format analysis, the Vertical Mapper module was used. Flooding areas were modeled considering the original values calculated by the Environmental Agency, which were validated after the passage of Hurricane Sandy through Santiago. The variables shown in Table 1 were incorporated into the studies.

Extreme floods through the years 2050 and 2100 s were calculated by the sum of the values of the SLRCC as a permanent flood scenario, and those obtained with the possible flood which may occur before a category V hurricane, (see Table 2).

For the analysis of the impact of sea level rise due to climate change in the area under study, the southeastern block of Cuba rise of 1 cm per year is taken into account (IGP 2010) while there are sectors lowering 0.1 mm per

Coastal Flood Hazard Mapping, Table 1 Calculation of the value of sea level rise (SLR)

Year	Estimated for CUBA (CITMA 2013)	Equinox high tide	Neotectonic	Final value of the SLR
2050	27.0 cm	50.0 cm	0.9 cm	77.9 cm
2100	85.0 cm	50.0 cm	0.9 cm	135.9 cm

Coastal Flood Hazard Mapping, Table 2 Calculation of the extreme SLRCC value at the PECUIM – Chivirico

Extreme situation with a category V Hurricane			
Valor del SLR (m)			
Year	SLR value due to climate change (CC h)	Category V Hurricane (HCT – V)	SLR value due to CC + HCT – V
2050	0.779	5.35	6.13
2100	1359	5.35	6.71

year, as is the case of the coastal settlement of the PECUIM Chivirico (Arango 2014). For this research both results are taken into consideration; and therefore, the resulting rise of 0.9 mm per year is the value that is used. As a final result of the first case study, four flood maps are provided taking different hazards into consideration (see Fig. 4).

The second case study corresponds to the flood scenario due to heavy rains for the province of Santiago de Cuba, which is located in the southeastern region of Cuba. In this case, the analysis is made 1:25,000 scale in the 11 municipalities of the province, where only two of them are coastal (Santiago de Cuba and Guama).

For hazard mapping, with the aid of the GIS, the layers of susceptibility factors or the scenario of occurrence of the hazard are combined with the trigger factor layer, which in this case corresponds to the isoyetic maps made for the three periods of return evaluated (5%, 10%, and 50% of probability). These periods consider the maximum daily rainfall that occurs in 24 h. The classification of the rainfall factor intervals is shown in Table 3.

For each return period, a rain map is obtained. This map is linked to the scenario of occurrence of the hazard. The multiplication of the layers is carried out considering ranges and weights established in the development of the research, with those obtained in the classification of the intervals of the rain factor in Table 3. The results of this combination provide the intervals for the classification of the hazard in Table 4. Finally, from this classification, different flood hazard maps for the different return periods are drawn up (see Fig. 5).

The province of Santiago de Cuba has an area vulnerable to flooding due to heavy rains of 401.7 km², which constitutes 6.5% of its total. Floods due to heavy rains occur mostly in

Coastal Flood Hazard Mapping, Fig. 4 (a) Area prone to flooding due to heavy rains in the PECUIM Chivirico; (b) area prone to flooding due to category I, III, and V hurricanes; (c) area prone to flooding as a consequence of sea level rise by 2050 and 2100 due to climate change;

(d) map of coastal flood hazard areas due to storm surge in categories I, II, and V hurricanes, combined with heavy rains and sea level rise due to climate change by the year 2100

municipalities with broad plains, low terrain and low permeable soils; among them, the two most affected and most extensive areas are the non-coastal municipalities of Mella and Contramaestre (Brito et al. 2013).

The floods in the coastal municipalities of Santiago de Cuba and Guama are smaller. These are produced mainly in the low areas and cones of dejection of the main rivers. In this area, the rivers have short courses and small basins. The inclination of its

Coastal Flood Hazard Mapping, Table 3 Classification of the rain-fall factor

Rain intervals in 24 h (mm)	Assigned value	Qualifier	Code on the map. Id
Greater than 401	4	High	3
Between 201 and 400	3	Medium	2
Less than 200	2	Low	1

Coastal Flood Hazard Mapping, Table 4 Classification of the areas according level of danger

Ranges	Qualifier	Color on the map
0–6.6	Low	Green
6.7–13.2	Medium	Yellow
13.4–20	High	Red

slopes accelerates the runoff caused by the large accumulation of water in the low areas and, consequently, leaves large amounts of soil and materials of various origins behind, which interrupt road traffic and isolate these territories.

For the return period of 2% (Fig. 5a), the dangers associated with heavy rains for most of the territory of the province of Santiago de Cuba display a behavior that oscillates between medium and low values. The northwestern zone of the Santiago de Cuba bay has a high risk of flooding due to the presence of low areas and the confluence of four rivers of great importance for the municipality.

For a return period of 10%, the hazards associated with heavy rains have a more homogeneous behavior (Fig. 5b). This allows a large part of the territory to have low danger values. The areas located in the northern portion of the province are the most extensive. The areas

**Coastal Flood Hazard Mapping, Fig. 5** (a) Flood hazard for a return period of 2 years; (b) Flood hazard for a return period of 10 years; (c) Flood hazard for a return period of 20 years (Source: Modified from Brito et al. 2013)

characterized as moderately dangerous are distributed punctually in different places of the province; although, in the central part, the greatest extension for this range of danger is observed.

Those areas with a high hazard level are reduced to smaller sectors and are highlighted mainly on coastal areas. In this sense, the dejection cones of the six rivers – namely, *La Magdalena*, *La Plata*, *Uvero*, *Guama*, *Sigua*, *Baconao* – stand out.

For a return period of 20%, the dangers associated with heavy rains have a more balanced behavior, which is characterized by low risk values in a large part of the territory (Fig. 5c). Those areas characterized with moderate danger are distributed only in small scattered sectors of the territory and mostly in the areas of the bay of Santiago de Cuba, (see Fig. 5d). The areas with a high danger are reduced to only three coastal sectors: *Guamá*, *Sigua*, and *Baconao*.

Conclusions

Coastal flood hazard mapping helps in analyzing different hazard scenarios in the coastal zone, coastal urban areas, and river basins. In the case studies integrated in the river basin, two different types of coastal floods are mapped which often occur in a combined way: (1) from the sea to land (when the river flows into the sea) and (2) from the land to the sea (when the sea makes its way into the mouth of the river).

Mapping methods and CoFHaM tools are available to help urban planners and decision-makers not only to make effective use of the data but also to provide new knowledge to minimize risks. Flood maps play an important role in raising awareness among the population and urban planners concerning the different types of flood hazards in order to lay the groundwork for preparing responses to emergency situations.

The two case studies analyzed were developed in the same coastal province of the Cuban archipelago. Results achieved allow us to conclude that the CoFHaM tool is effective to determine different types of hazards through the use of varied scales and levels of action (e.g., from province to municipality or locality) with scales from 1:2000 to 1:25,000.

The first case study analyzed in Cuba ratifies the vulnerability of the archipelago to the forecasts of the rise of the mean sea level due to climate change, where maximum values of ascent of 0.59 m are proposed, for which adaptation and mitigation measures are needed for its confrontation. Furthermore, in the first case study analyzed, the hazards associated with coastal flooding due to combined hazards are classified into six parameters: extreme, very high, high, moderate, little, and low; while the results of the second case

study of coastal flooding due to heavy rainfall in the different periods of return (5, 10, and 50 years) are based on four parameters: high, moderate, low, and no danger.

Coastal Hazard Indicators

Óscar Ferreira

FCT/CIMA, Universidade do Algarve, Faro, Portugal

Definition

A coastal hazard indicator is a measure of the state of coastal systems in relation to a given hazard, synthesizing complex information in a simple and resumed format. Coastal hazard indicators are commonly used to prioritize coastal vulnerability or assess the potential (or effective) impact of storms and should be used to facilitate coastal management actions. These indicators are often based on a parameter or set of parameters that characterize the coastal area, the driving mechanisms acting at the coast, or the interactive processes between coastal morphology and the underlying driving mechanisms. The coastal hazard indicators can, therefore, be classified into geoindicators, driver-based indicators, and process-based indicators.

Introduction

The understanding, analysis, and characterization of storm-induced hazards, such as coastal erosion or flooding, are extremely relevant for increasing the safety and reducing impacts of exposed population in coastal areas. Coastal hazards, namely, erosion and flood, are among the ones that generate more concern when analyzing the potential impacts of marine climate change, as expressed by a survey of 10,000 European citizens (Buckley et al. 2017). In a context of climate change, with sea level rise and changes in storminess, associated to the increasing occupation of the coastal areas, risks are also expected to increase in the future (van Dongeren et al. *in press*). The characterization of risks in a simple yet scientifically sound way can be performed using indicators of both hazard and exposure

(occupation). Coastal hazard indicators have been widely used for a long time (see Bush et al. 1999), based on multiple strategies and without a generic agreement or rule on the indicators to be employed. A large set of coastal hazard indicators can be found at the scientific literature, including morphological characteristics, wave and sea level parameters, and coastal evolution, among many others. The most commonly used parameters describe either the mechanisms acting over the coastal zone (driving mechanisms) or the coastal morphology/geology. The use of integrated parameters, which represent the processes associated with coastal hazards acting at the shore, is still in its infancy (Ferreira et al. 2017). A coastal hazard indicator should also integrate an associated time-scale (or return period), allowing a perception of the hazard potential evolution/change over time or within a specific time frame. Davidson et al. (2007) stated that an indicator must facilitate a management process, and, if that essential condition is not met, the term variable should be used instead. Thus, the main objective of coastal indicators is to support coastal management actions by synthesizing variables, processes, and information. In fact, coastal indicators have been used as tools to aid coastal management in the past, aiming to promote the interaction between coastal researchers and managers (Carapuço et al. 2016).

Storm-related coastal hazard indicators have been the subject of recent literature reviews by Carapuço et al. (2016), Nguyen et al. (2016), and Ferreira et al. (2017). Carapuço et al. (2016) identified and summarized the use of geoindicators. Nguyen et al. (2016) analyzed the use of all types of coastal vulnerability indicators, including geoindicators, hydrodynamic indicators, and coastal evolution indicators. Ferreira et al. (2017) reviewed the most relevant process-based indicators for the assessment of flood and erosion hazards in coastal areas.

Geoindicators

Coastal geoindicators refer and describe the physical/morphological features of coastal systems. For large-scale approaches, as the pioneer study of Gornitz et al. (1991), the geoindicators can be grouped into geology (expressing the relative resistance to erosion) and landforms (expressing the coastal type). A large number of geoindicators have been used, but several inconsistencies on their employment difficult the establishment of a coherent and common framework for their use. Carapuço et al. (2016), on their review, defined a framework for coastal geoindicators at sandy shores, providing details and insights on their use. These authors reported 43 indicators, targeting 16 coastal features, and were able to define a single and consensual criterion for the

majority of the sandy coastal features (for additional information on their use, see also Table 1):

Sandy environments in general: shoreline/coastline position, shoreline/coastline evolution, and sediment size/composition

Beaches: elevation, volume, width, and slope

Coastal dunes: elevation, volume, and width

Coastal barriers: elevation, volume, and width

Bush et al. (1999) included other geoindicators such as dune (alongshore) configuration, bluff configuration, or position relative to inlet location. These authors presented, however, a broader vision of the geoindicator concept with the inclusion of parameters such as erosion rate (a process-based parameter), the role of vegetation (an ecological-based parameter), or the existence of engineering structures (a result of human intervention). On rocky coasts, geoindicators also integrate the geological resistance (lithology and fracturing), the presence/absence of shore platforms, or the cliff height.

Driver-Based Indicators

Driver-based indicators are also commonly used to assess coastal vulnerability, namely, at large-scale applications involving semiquantitative coastal indexes (e.g., scaled in classes from 1 to 5 or from very low to very high). These indicators include the driving parameters related to wave characteristics, sea level, or wind. A compilation of the most commonly used driver-based indicators (namely, the hydrodynamic ones) and examples of their employment are provided at Nguyen et al. (2016). Driver-based indicators include (for details see Table 1):

Wave characteristics: height (e.g., average, significant and maximum), period, direction (exposure), storm energy, and storm duration

Sea level: relative sea level change, storm surge height, and tidal range

Wind: intensity/speed and direction

In contrast to the geoindicators, which exhibit alongshore shifts at a small spatial scale (meters), the variability of driver-based indicators (e.g., offshore wave characteristics, tidal range, wind characteristics) occurs at a larger alongshore spatial scale (tens to hundreds of kilometers). However, exceptions can occur at coastlines with a marked alongshore variability, such as the alternation of embayments and headlands, which often show a great variability on the exposure to waves and winds.

Coastal Hazard Indicators, Table 1 Comparison between computation type, return period calculation, short- (meters) to large-scale (tens to hundreds of kilometers) longshore variability, and inland expression of the hazard for selected geoindicators, driver-based indicators, and process-based coastal hazard indicators (Adapted and extended from Ferreira et al. 2017)

Indicator type	Indicator name	Computation type	Return period	Longshore variability	Inland hazard extent
Geoindicators	Shoreline position	DM/CE	No	Short scale	No
	Grain size		No	Short scale	No
	Barrier/beach elevation and width	DM/CE	No	Short scale	No
	Beach/coastal slope	DM/CE	No	Short scale	No
	Erosion rate	CE/F/M	No	Short scale	Yes
Driver-based indicators	Wave height	I/H	Yes	Large scale Short scale ^a	No
	Storm energy	F	Yes	Large scale Short scale ^a	No
	Sea level changes	F/M	Yes	Large scale	No/yes ^b
	Tidal range	I/H	No	Large scale	No
	Surge height	I/H	Yes	Large scale	No/yes ^b
	Wind speed	I/H	Yes	Large scale	No
Process-based indicators Overwash	Overwash depth	F/M	Yes	Short scale	Yes
	Overwash potential	F/M	Yes	Short scale	No
	Overwash extent	F/M	Yes	Short scale	Yes
Process-based indicators Flood	Flood depth	F/M	Yes	Short scale	Yes
	Flood extent	F/M	Yes	Short scale	Yes
Process-based indicators Erosion	Shoreline/berm retreat	F/M	Yes	Short scale	Yes
	Dune foot retreat	F/M	Yes	Short scale	Yes
	Vertical erosion	F/M	Yes	Short scale	Yes

CE cartographic extraction, DM direct measurement, F formulation, H hindcast, I instrumental, M model

^aRequires wave propagation models to include detailed longshore variability near the coastline

^bUsing a bathtub approach (or other flood extension approach) in association with the expected sea level change

Process-Based Indicators

Process-based indicators represent, in a simple way, the interaction between driving mechanisms and the coastal morphology and can be applied from large-scale to detailed approaches. These indicators are obtained through formulations or models that combine the driving variables (e.g., wave height, sea level) and the morphological parameters (e.g., berm height, beach volume). The resulting indicator has a physical meaning, directly related to the hazard, for example, the flood depth for coastal flooding or the shoreline retreat for storm-induced erosion. Process-based indicators are also able to discriminate the inland extent of the hazard, allowing the spatial (along- and cross-shore) representation of the coastal hazard. Process-based indicators, as most driving-based indicators, can be subject to a probabilistic analysis allowing the expression of their variability as a function of different return periods. Ferreira et al. (2017) suggested a set of process-based indicators for the assessment of hazards at sandy shores (for details on their use, see Table 1):

Overwash: depth, potential, and extent (Fig. 1)

Inundation: depth, extent, and discharge volume

Erosion (storm induced): shoreline/berm retreat, dune foot retreat, and vertical erosion (Fig. 2)

The authors also included recommendations on the use of these indicators and suggested formulas and models for their computation.

Process-based indicators can also be established for rocky coasts, as it is the case of the maximum width (inland extent) of cliff mass movements (see Teixeira 2006). This parameter can be used as an indicator that integrates all driving processes acting at the cliff and its geological resistance, being possible to establish return periods based on statistical analysis.

Summary and Final Considerations

Coastal hazard indicators have been often applied around the world to assess coastal vulnerability. The most commonly used indicators can be categorized into:

Geoindicators: related with the physical/morphological characteristics of the coastal zone

Coastal Hazard Indicators,

Fig. 1 Visualization of process-based indicators expressing overwash. Maximum overwash/overtopping depth over a seawall (*dashed black line*) and overwash extent (*solid black line*) at Fortaleza (Brazil) during a storm. Both indicators present a strong longshore variability, particularly the observed overwash depth

Coastal Hazard Indicators, Fig. 2 Visualization of process-based indicators expressing storm-induced erosion. Dune toe retreat (*solid black line*) and vertical erosion (*dashed black line*) at Fuseta Beach (Algarve, Portugal) after a major storm in March 2010. The dune toe

retreat includes an inland extent of the hazard, for the given storm (or associated return period). The vertical erosion shows a strong longshore variability as a function of changes on the natural dune height and effects of dune lowering by existing occupation

Driver-based indicators: an expression of the properties of the forcing elements acting at coastal areas

Process-based indicators: integrate driving mechanisms and coastal morphology representing the impact of the processes over the coastal forms

Most geo- and driver-based indicators are easy to obtain, since they can be extracted from existing cartography

(maps, digital terrain models, etc.) or instrumental measurements (or hindcasts), respectively (Table 1). These indicators can be translated into semiquantitative values (e.g., 1–10 scale), and their alongshore spatial distribution can be mapped, being a simple and often used proxy to express the alongshore changes in coastal vulnerability. They do not include the processes acting and transforming the coastal morphology, and, thus, they do not

represent the interaction between the morphology and the driving mechanisms. As such, geo- and driver-based indicators cannot be used as direct indicators of most hazards acting at coastal areas, such as overwash, inundation, or storm-induced erosion.

Process-based indicators use geo- and driver-based information and formulas to obtain a final representation of a given hazard, in association to a specific return period (Table 1). The use of process-based indicators implies a higher degree of expertise and, therefore, can reduce their applicability. Yet, these indicators allow an improved characterization of the hazard alongshore variability and often also include the cross-shore (inland) expression of the hazard (Table 1).

There is currently no universal application of coastal indicators or widely accepted intervals to classify each indicator according to the potential hazard (Carapuço et al. 2016; Ferreira et al. 2017). The lack of standardization of concepts and assumptions restricts the compared use of indicators among coastal areas (Nguyen et al. 2016). The selection of the appropriate indicator and associated thresholds is, however, fundamental to obtain proper hazard estimations. Thus, future studies addressing the classification, standardization, and definition of uses of coastal hazard indicators are required. Coastal hazard indicators should remain simple, unambiguous, and reproducible over different coastal types and regions. Indicators should be based on consistent methodologies, enabling the comparison across sites and expanding their usefulness for supporting coastal management actions.

Coastal Hoodoos

Shin Wang

Department of Geography, National Taiwan University, Taipei, Taiwan, ROC

Introduction

Hoodoo is a descriptive and collective term used by Thornbury (1969) to describe such topographic forms as columns, pillars, and toadstool rocks of bizarre shapes. He recognized that differential weathering helped to develop and modify such outstanding topographic forms. In Bryan's study (1925), he also concluded that those he studied in the southwestern United States were chiefly the work of rain-wash plus effects of mechanical and chemical weathering. Basically, the term bears no genetic meaning, but was used as a descriptive term to describe those small landform features of odd shapes. Hoodoos occur in various environments and are associated with many different types of rocks. Previous studies of such hoodoos indicated that differential weathering almost always played an important role in sculpturing their forms. Hoodoos often became a scenic attraction rather than a geologic subject to be appreciated by visitors. Near Tuscon, USA, on the way to Mt. Lemmon, from Windy Point to Geology Vista, highly weathered granitic rocks

display hoodoos by the roadside. The place became a vista point and the hoodoos became an attraction for visitors to stop and take pictures. Actually, wherever hoodoos were found, whether they occurred in deserts, on coastal platforms, at the edge of highly dissected terrain or at riverbanks, they often became a site for visitors' appreciation. They are almost always recognized as earth's miracles and definitely as earth's heritage sites. In this regard, hoodoos are more of an artistic and aesthetic subject than a geological phenomenon.

Coastal hoodoos are relatively well studied. Trenhaile (1987) and Ollier (1984) described in detail the processes that caused the formation of hoodoos on coastal platforms and other coastal environments. Trenhaile pointed out that salt weathering which includes hydration, thermal expansion, and crystallization of various salts are important to form such features as tafoni and honeycombs.

He also pointed out that honeycombs are best developed in the zone above the level of normal wave action, but that periodically experiences heavy spray and splash during stormy weather. Bartrum and Turner (1928) first drew attention to the lowering, smoothening, and leveling of inter-tidal rock platforms by weathering processes apparently associated with pools of standing water. Water layering weathering includes alternate wetting and drying (slaking), salt crystallization, and many other chemical weathering processes. Collectively, they serve as a delicate process to sculpture hoodoos. Case hardening which often accompanies water layer leveling on platform surface often causes the formation of boxwork or frame-like patterns and weathering pits, which have raised rims. Some pits resemble miniature volcanoes with water-filled craters (Ollier 1984). He described elevated pits from Cape Patterson, Victoria as follows: "Small pits are filled by the tide or by rainwater and this keeps the immediately surrounding rock wet, while the platform around is reduced in height by wetting and drying. Eventually the pits comes to be like a miniature volcano with the crater filled with water and so kept wet, rising above a miniature plain which occasionally dries out." Other papers which described water layer weathering and salt weathering include Evans (1970), Gill *et al.* (1981), Goudi (1993), Mustoe (1982), Wellman and Wilson (1965). Pedestal rock is another type of hoodoo often seen in the coastal environment. Pedestal rocks are mushroom-like rocks, which are projections of solid bed-rock formed by flaking and hydration in a desert environment (Ollier 1974). Ollier also described pedestals from Cape Patterson, Victoria, and indicated that they were formed by blocks of arkose resting on a coastal mud-stone platform. Hills (1971) described similar features formed by a fallen block lying on a platform and

others formed by large calcareous concretions that now stand on pedestals above a water-layer lowered platform surface.

Hoodoos in Yehliu, Taiwan

Such hoodoos, including elevated pits, pedestals, tafoni, honeycombs, and others are well developed in the Yehliu Scenic Area in Taiwan. These hoodoos were studied by Hsu (1964), Lu (1978), Wang and Lee (1984, 1994), Hsu (1988), Hong and Huang (2001).

The most abundant hoodoos in Yehliu are pedestals, which are locally called mushroom rocks. One of the pedestals looks like a western queen's head and was called the Queen's Head (Fig. 1). Next to the pedestals is a layer with many Ginger Rocks, which are stand-up calcareous concretions originally occurring in a thin bed (Fig. 2). It is quite significant for so many concretions, widely distributed, but limited to a bed of less than 1 m.

Coastal Hoodoos, Fig. 1 Queen's Head, a pedestal rock

Coastal Hoodoos, Fig. 2

Ginger rocks, which are concretions stand out after lowering of adjacent ground

**Coastal Hoodoos, Fig. 3**

Candle rocks, which are elevated pits as described by Ollier (1984). At the very center is a concretion

This thin bed is the key bed that can be used for tracing and correlation of sedimentary strata. Candle Rocks are lower in the sequence stratigraphically (Fig. 3). They belong to another sandstone bed with randomly distributed concretions. Concretions exposed often led to the formation of elevated pits after uplifting and erosion. Furrows developed around the concretions, which were filled with water frequently. Surrounding the furrows is a zone of hardening which became relatively raised. After further uplifting, the Candle Rock becomes higher and an apron-like fringe area developed gradually. As a whole they are elevated pits as described by Ollier (1984). The

size of the Candle Rocks found in Yehliu may reach a height of 1.5–2.0 m, and a diameter of 2 m.

Geology of the Pedestal Rocks in Yehliu, Taiwan

The Yehliu coastal scenic area is located approximately 15 km to the northwest of Keelung City, Taiwan. The area is a promontory, approximately 1.5 km long and only about 400 m wide. Part of the promontory is so narrow that it is actually penetrated by sea caves or narrow openings along joints.

Strata exposed in Yehliu area are mainly bedded sandstone of Miocene age. These tilted strata strike N40E and dip at an angle of 18°–22° to the SE. The strata can be subdivided into eight units based on their lithological and morphological characteristics. Many sandstone beds are calcareous and rich in concretions. Pedestal rocks are mushroom-shaped, with a resistant head rock supported by a neck rock made of an underlying, less resistant rock. In general, a pedestal rock is 1.5–3 m high and composed of a head, a neck, and a base. The spheroidal head is 1.5–2 m in diameter and honeycombed. The neck, instead, is smooth-surfaced and thinner than the head. The distribution of the pedestals is clearly lithologically and stratigraphically controlled. They form a parallel and linear array regularly arranged on the tilted shore platform. The thin, calcareous sandstone bed in which the pedestals occur is tilted and protected from direct wave attack by another set of sandstone beds, which form small ridges. From top to bottom the upper rows of pedestals are about 2–4 m above sea level, and the lower pedestals are just above the sea level. The same sandstone bed exhibits no signs of pedestal development under the sea surface. A closer look at the pedestals clearly reveals that these pedestals start to develop once they left the sea surface. Gradually they became separated blocks to form pedestals with no neck, then with a thick neck, and then with a thin neck. Finally the neck broke, the head fell and the pedestal's life ended. The plane which connects the top of the pedestals inclines at an angle of 17°–20°, whereas the surface (actually the shore platform) which connects the bottom of the pedestals has an inclination of about 11°–13°. This is another indication that pedestals grew taller and higher as the shore platform was weathered lower. Those parts that rose above the sea earlier were weathered more. The pedestal rocks, which are higher in elevation, are taller and usually have a thinner neck. Those that stand lower are short and have a massive neck. The height of the pedestals are 1.5–3 m. The tallest is about 3.5 m. The diameter of the head may reach 1.6 m. The spaces between the pedestals average to a distance of 2–3 m. The total number of pedestals is about 180.

Owing to weathering of the calcareous sandstone, the surface crust of the head is dark colored compared to other parts of the pedestal and to those parts of the same bed below the sea level. Gauri (1978) gave a good explanation of the weathering process which formed such a dark-colored crust on a lime-rich rock.

Physical properties of the head and the neck of the pedestals are studied both in the field and in the laboratory. As a result of various means of mechanical tests, such as the Schmid Hammer Test, Slaking Durability Test, and Point Load Test, it is known that there is a difference in the physical strength of the different parts of the pedestals. The head of the pedestals is of much greater strength than the neck.

Water absorption by the head is also slightly lower than the neck, which indicates that the neck rock may have more open crevices that allow water to penetrate.

Microscopic study of thin sections of rock specimens from different parts of the pedestal also reveal important information. The head rock is composed of well-sorted quartz grains cemented mainly by calcite. The neck rock is composed of less well-sorted quartz grains but cemented by calcite and iron minerals. Thin-section study of the surface crust of the head rock, which is darker in color and honeycombed, indicates an enrichment of calcite and clay minerals as cemented materials (Wang and Lee 1994; Hong and Huang 2001). The result of microscopic study again supported the interpretation by Gauri (1978).

Wang and Lee (1984, 1994) in their study, concluded that differential weathering, including alternate wetting and drying, salt crystallization and other chemical processes accompanied by uplifting and erosion are responsible for the formation of the pedestals. Based on coral reef dating, estimated uplift rate of the area (about 2 mm/year), elevating of the red oil-painted safety markers on the platform (which is about 1–4 cm above the adjacent ground, and the first time the park placed the paint is about 50 years ago), and other evidences such as the height and the spacing between the pedestals, Wang and Lee (1984, 1994) estimated that the age of the pedestals is not more than 4000 years since their first appearance above the sea level.

Coastal Lake Systems

Anja M. Scheffers¹ and Dieter H. Kelletat²

¹Southern Cross University, Lismore, Australia

²Institut für Geographiedidaktik, Fachgruppe der Didaktiken der Mathematik und der Naturwissenschaften, Universität zu Köln, Cologne, Germany

Definition

To fulfill the definition being a “coastal lake” *sensu lato*, at least one property of a lake should have a relation to “coasts” or “oceans,” e.g., (part of the) form, sediments, characteristic of the water, hydrodynamics (e.g., tides), or organisms. These lakes often exhibit bottom and shore topographies solely deriving from the basin-forming process. A coastal lake *sensu stricto* should be in a long period of its history a part of the sea, either in its early time, or in its younger existence and into the future. The latter generally are termed “lagoons,” and many of them still have a (natural) connection to the open sea. Lagoons in most cases have an ocean-side barrier (barrier bars, barrier islands, spits, beaches, beach ridges, dune belts) formed by marine/littoral sediments and processes. These began to grow with slowing down of the postglacial sea level rise around 7,000 years BP (Anima 1990; Antikueira et al. 2005; Aritzegui and Wildi 2003; Carvalho do Amaral

et al. 2012; Dias and Fernande 2006; Dillenburg and Hesp 2009; Giannini et al. 2007; González-Villanueva et al. 2015; Hein et al. 2013; Kaiser et al. 2012; Longhitano et al. 2016; Otvos 2005; Peek et al. 2014; Perillo et al. 1999; Scheffers et al. 2012; Scheffers and Kelletat 2016; Tagliapietra et al. 2009; Toldo et al. 2000).

Forms and Types of Genesis

Depressions housing coastal lakes may have in their genesis no relation to marine or coastal processes being of volcanic/structural, glacial, periglacial or fluvial origin, getting their relation to the sea by tectonic uplift or subsidence, glacioisostatic emergence, or general (eustatic) sea level variations (Figs. 1, 2, and 3).

Coastal lakes with spatial and genetic relation to coastlines may occur in all latitudes and worldwide. As a lake (or pond) needs a depression filled with water, all exogenic processes actively forming depressions (like wind with deflation, glaciers with erosion, karst with solution) may leave basins. Along (formerly) glaciated coastlines, they are abundant in rocky landscapes emerged and emerging by glacioisostatic uplift. Other processes do not initially form depression but may leave basins by blocking originally open depressions like valleys by beaches, beach ridges, or coastal dunes. A high number of coastal lakes exist along sedimentary and low coastal relief, and their size may reach thousands of km².

Coastal lake basins may be closed by coral reef construction, eolian deposition, beach ridge systems like barriers and spits, as open spaces between ridges during delta progradation, or blocked by sea ice pressure on beaches (Figs. 4, 5, 6, and 7). The closure of lagoons in most cases are built by marine (and littoral) processes using (fine) sediments from the upper shelf in a direction to a former coastal indentation, or block openings by longshore drift.

Water Movements and Segmentation

Many coastal lakes and lagoons are isolated from the open sea. Nevertheless, their proximity to the ocean, a low relief, and in particular a large size of open water (or the longest lake axe in direction of strong winds) allow waves to initiate longshore drift processes along with their shorelines so far as these are not occupied by wetlands. Spits develop often in a rhythmic pattern (Figs. 8, 9, and 10), and a segmentation of the lagoons may be the result. Winter ice cover moved by strong winds also plays a role in this process, and some of the individual water bodies originate from thermokarst features in high latitudes.

Coastal Lake Systems, Fig. 1 Coastal lakes deriving from endogenic (structural) control. (a) 22 km long lake on the San Andreas Fault, Point Reyes, California (USA), closed in the north by beaches and dunes. (b) Lake Maracaibo, a structural depression between folded mountains in NW Venezuela, >13,000 km² large, with a connection to the Caribbean via an old valley but blocked also by young Holocene beach ridge systems. The lake belongs to the oldest in the World (>20 Mio years). Max. depth is 60 m. Semidiurnal tides enter the lake and bring salt water to the northern parts, while the southern sections are fed by freshwater streams. Strong oil drilling results in a significant subsidence of the

eastern coastal section of up to 0.2 m/year. Scene is >400 km wide. (c) Belcher Islands in the SE of Canada's Hudson Bay are wide foldings cut and polished by Ice Age glaciers. They contain many lakes of different forms and openings to the sea along less resistant rock layers. The whole scenery (120 km wide) is rising from the sea since thousands of years. (d) Along the Kimberley Coast of NW Australia, long-term down warping of the land and Late Holocene sea-level rise have flooded structural depressions. Their entrance for seawater is two "horizontal waterfalls" as tidal range here is very high. Scene is 10 km wide (Credits: Google Earth)

Suspension, Soluble Matter, and Sediments

Lagoons fill depressions in the coastal landscape, and as thus, they have a function as sediment traps (Adomat and Gischler 2015; Carreira et al. 2011; Carvalho do Amaral et al. 2012; Murray and Mohanti 2006). These sediments may come from the terrestrial catchment area via rivers and hill-wash (the

latter in particular with soil sediments after forest clearance and land use), or as organic sedimentation from flora and fauna in the lagoons. Eolian deposition (deriving from beaches along the barriers, sometimes as shifting dune belts) also contributes to sediment infill. Sediments from the sea, either via openings in barriers by tidal currents, or by storm wave (and tsunami) wash-over processes may mark specific

Coastal Lake Systems, Fig. 2 Coastal lakes originating from non-coastal processes. (a) Two coastal lakes of volcanic origin on the Galapagos archipelago (Ecuador): the small one dammed by a crater ring of tephra, permeable for sea water; the larger one – once open to the ocean – blocked by a younger lava also permeable for sea water. Scene is 7 km wide. (b) Karst depression (small poljes) at the Croatian coastline, drowned by postglacial sea-level rise via river-like connections to the sea.

Scene is 30 km wide. (c) In the cockpit karst landscape of the Rock Islands of Palau (Micronesia), many lakes are connected to the ocean by karstified joint patterns or even caves, and marine organisms (e.g., millions of jelly fish) may live in these lakes now. 6 km wide scene. (d) In a glacier-sculpted landscape of northern Norway, lakes emerged from the sea by late- and postglacial glacioisostatic uplift. Their level now is between 1 and 44 m asl (scene 18 km wide) (Credits: Google Earth)

event layers in lagoonal geoarchives (Atwater and Moore 1992; Bondevik et al. 1997; Chaumillon et al. 2017; Fitzgerald and Miner 2013). The physical isolation from the ocean prevent lagoon sediments from disturbance by waves, but their proximity to the ocean also allows to record specific and extraordinary events. Coastal processes including sea-level variations, therefore, are stored in lagoons often in detailed records, and in the case of seasonal climates, even with wave-like layers in the resolution of months, supported by palynology using precipitation of pollen. Paerl et al. (2006) studied the influence of hurricane impacts of the last decades in Pamlico Sound (east coast of USA), and Grand Pre et al. (2011) identified warm periods with sea-level rise impulses from the content of benthic foraminifera in Pamlico Sound and planktonic foraminifera from the Gulf Stream in sediment cores. Maddox et al. (2008) found an 11,600-year long history of sea level, salinity, sediment, and nutrient changes in the Matagorda and Lavaca estuary complex of Texas (USA).

As long as in suspension, the color of lagoonal waters may indicate the origin of the sediment input (Figs. 11a, b), while vivid coloration may point to soluble matters (Figs. 11c, d). Chemical deposits even occur at the surface by evaporation in semi-arid and arid climates as in salt pans (Fig. 12).

Water Budget, Evaporation, and Salt pans

The water budget of a lagoon depends from at least five different sources:

- Run-off from the terrestrial relief including river discharge.
- Fresh ground water (identifiable by its radon content, compare Sadat-Noori et al. 2016).
- In-flow from the sea by open channels.
- Percolation of seawater through barriers.

Coastal Lake Systems, Fig. 3 Coastal lakes from glacial, periglacial, and glacioisostatic processes. (a) Glacier lagoon (Jökulsárlón) at the site of a former Vatnajökull outlet glacier at the southern coast of Iceland (scene 12 km wide). Suspension particles in the water show a fine gyre. (b) Thermokarst lakes on permafrost in northern Canada partly opened to the sea by thermoabrasion (scene 10 km wide). (c) Lakes dammed by a

series of glacioisostatic uplifted beach ridge systems between sea level and 40 m of elevation in this 13 km wide scene along SW of Hudson Bay (Canada). (d) A combination of glacioisostatic uplift of beach ridges and thermokarst on permafrost along the coast of western Alaska (USA) left thousands of small lakes. Scene 100 km wide (Credits: Google Earth)

- Lastly wash-over from extraordinary events in the ocean like winter storms, tropical cyclones, or even tsunamis.

“Expenditures” of the budget are in the first order evaporation (depending on the relation of lake size and depth/water volume as well as climate) and – during high lake levels – possible percolation through barriers into the sea. Variations of lagoon levels also depend on tides and irregular sea-level oscillations by differences in air pressure or during storm surges.

Even if a lagoon is blocked from the open sea, salt spray and splash from storms rise salinity as does the fresh water from land during evaporation. The chemical composition allows to identify the source of saline deposits (evaporates) in lagoons with negative water budget (Fig. 12). Saltpans, often colorful by bacteria, are found in high numbers along all subtropical coastlines of the world.

Anthropogenic Changes

During potentially thousands of years of existence, lagoons may pass alterations from climate and sea level variations, but especially from anthropogenic impacts in much more intensity and shorter intervals (Anthony et al. 2009; De Wit 2011; Harris 2006; Pérez-Ruzafa and Marcos 2005, 2008; Pérez-Ruzafa et al. 2011; Schallenberg and Schallenberg 2012; Terrell 2002; Thompson and Flower 2009; Wazniak et al. 2007). These may have different causes, some of them indirectly (e.g., interference of river run off by reservoir construction, forest cleaning, agricultural measures in the catchment areas, acidification), many of them directly (e.g., artificial closures or openings, discharge of pollutants and eutrophication, economic exploitation for chemical industries, or aquafarming (compare Fig. 13). Tourism industry, boating, and fishing are other negative impacts on lagoonal

Coastal Lake Systems, Fig. 4 (a) SE coast of Egypt at the Red Sea with a shallow depression blocked by active reef growth (scene 7 km wide). (b) A deep basin blocked by a fringing coral reef at the Red Sea coast of NE Sudan (scene 30 km wide). (c) Flooded lower section of

valleys (limans) south of the Amazon delta in Brazil, blocked by active sand drift (scene 25 km wide). (d) Partly active coastal dunes block a lower river course to form a ria-like lagoon (a liman) at the east coast of China. Scene is 22 km wide (Credits: Google Earth)

ecosystems, as is the danger by invasive species. Flocks et al. (2009) present their results from an investigation of large Lake Pontchartrain in southeastern Louisiana: most contaminants come from roadways and agricultural sources, leading to degradation and decline of benthic organisms as shrimps and clams. They found a significant increase of trace metals (Cu, Pb, Zn, Ni) in a mixing zone of the upper 1 m of lake sediments, a depth to which bioturbation and water turbulence combine. Similar conditions are found in the Gippsland Lakes in southeastern Australia. These are freshwater lakes sometimes with salt intrusion when rainfall causes lake levels to rise and water breaks through the dune belt. They suffer strongly from land use and forest cleaning in

catchments as well as from wastewater discharges by urban development with pollution and increased nutrient loadings resulting in algal bloom. Habitat loss and destruction of freshwater wetlands by salt ingressions are additional impacts on lake ecosystems.

Main Factors in Ecosystems of Coastal Lakes

Coastal lake systems exhibit the same factors as all other lentic systems, more or less modified by marine influences (Chagas and Suzuki 2005; Coutinho and Seeliger 1984; Ferrarin et al. 2014; Gönenc and Wolflin 2004; Hennemann et al. 2011; Liu

Coastal Lake Systems, Fig. 5 Lagoons as young coastal lakes dammed by sediment deposition. (a) In a river delta in SE Turkey, a lagoon is fringed by beach ridges (scene 35 km wide). (b) On St. Vincent Island in NW Florida (USA), lakes occur in basins within

beach ridge sequences (scene 16 km wide). (c) and (d) in northern and eastern Siberia (Russia), lagoons are closed by ridges formed from sea ice pressure on beach gravel (c: 10 km wide scene (Detail: 2 km long), d: 2 km wide scene) (Credits: Google Earth)

Coastal Lake Systems, Fig. 6 A rare type of lagoons have long axes more or less perpendicular to the coastline. These are limans (from the Greek word for harbor). They fill the lower section of valleys carved during sea-level low-stands. The barriers indicate rather shallow water conditions, and the missing infill from fluvial sediments point to only

small transport competence of these rivers. The left example shows a 65 km wide landscape in eastern Russia; the right one documents a fine set of limans at the south coast of Martha's Vineyard on morainic deposits (Massachusetts, USA), in a 6 km wide scene (Credits: Google Earth)

et al. 2013; Lory et al. 2010; Paerl et al. 2006; Selig et al. 2007; Smol and Douglas 2007; Thomaz et al. 2008). Because of their shallow nature, they may have no profundal aphotic region but a littoral, benthic, and open water (limnetic) zone.

The physical parameters, as well as chemical factors, play all an important role, triggering – among others – trophic relationships. Hydrodynamics as well as water budget, however, may be strongly influenced by marine intrusions (of salt

Coastal Lake Systems, Fig. 7 (a) 15 km long spit at 60° N and 166° E in eastern Russia, protecting a young delta from waves and current. (b) 18 km long liman with spits growing from both sides in western Alaska. (c) Barrier islands with wash-over fans into a lagoon on Prince

Edward Island, eastern Canada. (d) An unusual seaward curving barrier at the northern shores of the Sinai Peninsula (Egypt) point to very shallow water conditions by sedimentation from the Nile delta. Scene is 85 km wide (Credits: Google Earth)

water, organisms, tides) and, because of its neighborhood to the open ocean, by strong winds, sea ice, and even tsunamis. Other factors, in particular temperature regimes, community patterns, and diversity, depend on latitude and types of climate.

Generally, the width and depth of an opening influence the amount of seawater, chemistry, stratification, and mixing in a lagoon, as well as tides and currents in the basin (Kirk and Lauder 2000). Intermittent openings and closures, depending on higher tidal range, are described by Liu et al. (2013) for SE Australian lagoons. Significant changes for the ecosystems are also found by Cheng (1981) for New South Wales lagoons (Australia), where high floods from the land may sweep away sandy barriers, followed by their constant rebuilding from high waves. This leads to salinity variations from freshwater to hypersaline conditions. All these factors influence mixing and nutrient balance of coastal lakes.

Lakes, in general, are classified according to the intensity and frequency of intermixing into at least eight different types:

Amictic are those without any significant turbulence because of (nearly) permanent freezing as in Antarctica, the high Arctic or in extreme mountain elevations.

Oligomictic lakes mostly have no full circulation and occur in tropical lowlands.

Meromictic lakes are only mixed in the surface water strata but not in deeper parts.

Holomictic lakes experience at least one full circulation per year.

Cold monomictic lakes as in polar and subpolar latitudes may have one full circulation in summer but no stagnation because of the brief period of the warm season.

Warm monomictic lakes occur in warm middle latitudes and the subtropics and have a significant stagnation time in summer. During cooling down to the winter period, homothermy happens and winds may easily mix the whole water column.

Dimictic lakes have two significant full circulation periods (spring and autumn) and two stagnation periods (summer and winter) and are found in the northern parts of North America and in eastern Europe.

Coastal Lake Systems, Fig. 8 Lagoon landscapes with internal segmentation of the water bodies by spits. (a) A 22 km wide scene from western Alaska. In the 5 km long southern section (b), thermokarst evidently has initialized lake building. (c) A narrow but long lagoon is segmented by rhythmic spits forming along the inner fringe of the

barrier, probably by lake ice movement and pressure processes. This scene in northeastern Siberia (Russia) is 25 km wide. (d) Significant segmentation in a 10 km long lagoon at the NE spit of Nantucket Island, Massachusetts, USA (Credits: Google Earth)

Coastal Lake Systems, Fig. 9 (a) This 30 km long lagoon in northeastern Siberia (Russia) exhibits a final segmentation by similar shaped individual lakes. Smaller lagoons along seaward barrier sections show similar forms in a smaller scale. Thermokarst on permafrost at 70°N and pressure by lake ice certainly have contributed to these patterns.

(b) Lagoa de Araruama in Brazil, 45 km long, is also segmented similar to arctic examples, but hereby spit building from longshore drift along the lakeside flank of the barrier, initiated by easterly winds (trade winds) (Credits: Google Earth)

Coastal Lake Systems, Fig. 10 One of the largest lagoons on Earth is 265 km long Lagoa dos Patos in southeastern Brazil. Forelands and spits occur along sedimentary lagoon shorelines, while the northern and southern section exhibit large areas of wetlands. Visible suspension of fine sediments give a lake color with diminishing intensity to the south, because its source is a river mouth in a northern estuary (Credit: Google Earth)

Polymictic lake types are fully mixed day by bay because of daytime climate as in tropical high mountain regions.

This classification in the first order is related to temperature regimes in the lakes. With the exception of *polymictic* lakes, all other types occur as coastal lakes. Their mixing processes, however, are hampered if brackish or saline waters are present. Because of their higher density, these tend to remain stable in the lower water levels.

The nutrient regime of a lake is generally classified into three categories: one concerning water budget, the second concerning sediment budget, and the third concerning nutrient turnover. Water budget implies the main material flows between the hydrosphere and the atmosphere, like input by precipitation and inflow, and output by evaporation and outflow. Sediment budget implies organic as well as inorganic sedimentation with the input of dissolved and particulate materials and their accumulation in the benthos with adsorption and desorption, as well as the exchange of dissolved materials between the water and the sediment by chemical and organic nutrient cycling and turnover. Bioactivity of

Coastal Lake Systems, Fig. 12 Hypersaline lagoons and salt pans: (a) A 3 km wide scene at 47° S in Patagonia (Argentina), (b) 36 km wide scene and 20 km long Lake Bonney (c) from southeastern Victoria (Australia). (d) Three parallel belts of hypersaline lagoons and (mostly)

inactive dune ridges in SW Australia. They represent three phases of Late-Pleistocene and Holocene sea-level high stands (Credits: Google Earth)

organisms in coastal lakes is distinguished in particular by material and energy cycling during production, consumption, and destruction.

An extended ecoregion including a variety of aquatic habitats can be found along the southeastern coastline of Brazil (Dillenburg and Hesp 2009), including Lagoa Mirim and Lagoa dos Patos as the largest coastal barrier-lagoon system in South America. These habitats comprise brackish-salt lagoons, freshwater bodies, swamps, marshes, seasonal freshwater ponds, and estuarine lower river sections. Further to the north, Lagoa de Araruama is hypersaline with salinity up to 5.6‰ (Kjerfve 1994) and also suffers from large amounts of anthropogenic nutrient inputs. Beauclair

et al. (2016) used mollusks in shell middens (*sambaquis*) around this lagoon to identify potential changes in environmental conditions over long time. They were triggered by climatic variations and sea-level movements in older periods, and by strong anthropogenic influence in the younger past. Principally, all factors (physical, chemical, abiotic, biotic) are strongly interrelated in natural environments and control the kind and health of lagoonal ecosystems. As artificial modifications in discharge areas are much stronger since the time of urban growth, industrialization, and agroindustries, they accelerate intensity and frequency of changes to the disadvantage of coastal lake systems.

an 8 km wide scene of China at 39° N. (c) Traditional aquafarming on fish and shrimps in a 3 km long lagoon at the south coast of Sumatra, Indonesia (Credits: Google Earth)

Important physical factors are light penetration (which depends on transparency influenced by suspension load and planktonic micro-organisms), temperature, and stratification depending on salinity, radiation, and mixing by wind and currents which potentially differ in the lake zones. An example for nearly perennial salt stratification is Lake Maracaibo (Venezuela), a rather deep (about 60 m) and one of the largest coastal lakes of the world. It is only disturbed in some way during the dry season with stronger winds and relatively weak river inflow (Laval et al. 2005).

Chemical factors are in the first order oxygen content (depending on depth, mixing, and life cycles) and phosphorus as the main determinant for primary production as well as for photosynthesis, plus carbon. Evaporates found in dry pans are the result of enrichment of solutes (mostly inorganic salts).

Biotic factors depend on physical and chemical ones as well as the interrelation of organisms (bacteria, algae, aquatic plants, zooplankton, invertebrates, fish, and other vertebrates) and their trophic relationship and food webs. Algal productivity generally is higher in waters with some salinity. This, however, may change in short periods as do accumulation of

nutrients deriving from soils and weathered rocks in lagoon watersheds.

Summary

The genesis and history of coastal lakes strongly depend on postglacial sea-level variations, either by flooding existing basins, damming coastal indentations by barriers built from sediments transported landwards from the upper shelf during a young transgression, or by longshore drift from nearby cliffs or fluvial sediments. Their history is archived in bottom sediments containing signatures of saltwater intrusions, which influence and limit biodiversity. These lakes (mostly called lagoons) can be classified according to their form and origin, age and relation to sea level, kind of water exchange with the open sea and salinity, or – like all lentic systems – to their water budget, stratification, circulation, or trophic character. Coastal lakes, in general, represent a young and shallow class of water bodies and often and intensively suffer from anthropogenic impacts like pollution and eutrophication from land use and urban areas in

their catchment area. Because of their worldwide distribution and extreme high number, research on coastal lake systems is still in its infancy.

Coastal Management Practices, Fig. 1 Essence of ICM: integration of sectors

Coastal Management Practices

Frank van der Meulen¹ and Bert van der Valk²

¹Frank van der Meulen Consultancy, Voorschoten, South Holland, The Netherlands

²Deltares, Unit Marine and Coastal Systems, Delft, The Netherlands

Rationale

Coastal management practices embrace a complex and broad subject, hard to cover in a short paper. This entry starts with general aspects. It continues with a number of management practice examples that give the reader a sense for the scope of coastal management in the twenty-first century. Our examples deal with coastal-plain sedimentary environments. These are and will be amongst the most vulnerable in the future. The main focus selected is not on traditional civil engineering designs, but rather on nature-based designs. In our opinion, they deserve wider attention as well as opportunities.

General Aspects

Coastal Management (CM)

Our coasts are of great ecologic, economic, and sociologic importance (e.g., Martinez et al. 2007). The essence of CM lies in the integration of these sectors (Fig. 1). Coastal management (often also called Integrated Coastal (Zone) Management, ICM or ICZM) is a set of human activities and techniques applied to direct (or keep) the coast, and its adjacent waters and land, in a desired direction or condition. CM integrates across the many sectors that have interests in the coast. From this perspective, it is a form of spatial planning that integrates planning, decision-making, and execution of concrete projects, based on an issue driven but integrated approach (e.g., Misdorp 2011).

Which kind of management practices is relevant for a coastal zone depends on the physical setting, the economic structure, and on the cultural heritage of the coastal

populations. Of special importance is how a particular governance system has evolved and how it works.

CM is important because coasts fulfil a wide range of functions for society. Some of these functions are conflicting with each other. For instance, nature conservation and socio-economic development often are conflicting. Moreover, coasts are under increasing pressure. It is foreseen that within decades, a much larger share of the world's population will be living in coastal areas where there is work, living space, and leisure. The process of CM starts with (future) requirements the local society has. This, in its turn, requires an integrated plan, directed at special issues as a general framework for measures.

Such a plan aims to prevent the development of various individual or site-specific separate plans, that are not related. The plan is made for a particular defined area to be managed. That area is characterized by distinct physical and ecologic properties and forms, (proposed) human activities, the acting governance system, and the way it developed. The CM plan is directed towards issues within this territory. An issue can be safety against flooding, or water pollution, or protection/development of valuable ecosystems (like coral reefs, mangroves, dunes, and beaches), or a combination of issues. CM is a cyclic process (Olsen 2003a). Loops may be followed more than once. Characteristic steps in a loop are: (i) issue identification and assessment, (ii) program preparation, (iii) formal adoption and funding, (iv) implementation, and (v) evaluation and feedback. During the cycle, an adaptive process takes place; there is growing interaction between the natural and the socioeconomic system. That is the reason why CM takes time, considerably more than separate plans and phases of government. This explains why the implementation of CM often is difficult (Olsen 2003b).

Management Practices

The world's coasts present a large diversity. Not only in natural habitats but also in cultural and governance settings, along with a wide variety of management practices. The aim of CM is always to work towards a sustainable development of coasts and their

populations. CM should be site specific and tailored towards the (cultural) history of the site. It means that CM cannot produce a general solution, as if there is just one recipe for all situations, even if the environmental conditions and issues are similar. In fact, the transfer of practices from one country to another (often done with the best intentions) needs great care, in order to be truly appreciated and accepted by the local applicants.

The impacts of climate change are becoming more and more understood. Processes of drastic coastal change (both environment and people) are upcoming. The traditional civil engineering approaches to coastal erosion and shoreline evolution were formulated in a past time of climatic stability. Facing a future time with major sea level rise, climatic instability, and more violent (rain) storms poses great challenges for humans and their management activities. Currently, ca. 60% of the world's population flock along coastlines, and this percentage is expected to rise further over the coming decades, prominently in Asian and African countries, putting large and increasing numbers of coastal inhabitants at risk of river and/or marine flooding (Neumann et al. 2015).

Coasts always are narrow fringes, along large land areas. Thus they can be easily disrupted, both from the sea side as well as from the land side. Because of the many pressures from both sides, the room for development along the coast becomes increasingly confined. The term “coastal squeeze” is coined for this process. It is a slow process, only noticeable after decennia of coastal development (Fig. 2). But while this goes on, characteristic coastal dynamics and biodiversity decrease and the natural “buffer” against flooding and erosion gradually disappears. Giving (back) room to the coast (and sometimes room for river dynamics) is, in some cases, a promising new avenue of practice. It reverses this process and restores coastal ecosystems and dynamics (see, for example, Esteves 2014). Room can be found either by giving up ground that is currently in economic use (going “inwards”) or by “extending the coastline

outwards” (see below, example “[The Netherlands, Southern North Sea Coast: ‘Building with Nature’ in a Sandy Environment](#)”). In any case, physical planning is crucial, especially in the case of an eroding coastline, which is the case in ca. 80% of the world's present coastlines.

Coastal practices often reflect the (history of) culture of coastal population. Back in history, when there were few coastal issues to deal with, there was hardly any management (necessary). Later on, management comprised a kind of “wait and see.” Actions were only taken in response to acute and local problems or hazards that occurred. This reactive attitude can, unfortunately, still be seen in many places in the world. With memory of a hazard (for example, a disastrous flood) fading over time, awareness in the minds of the people does so too, including the urgency to take measures.

More and more countries, though, tend to change their mind-set and develop proactive attitudes in CM. These countries want to anticipate imminent danger and be ahead of the problems. Proactive practices require measuring, monitoring, modeling, and evaluation, together with public education on the issues and their implications. The longer the time spans of measuring, the better the predictions on future changes, and the better the appropriate management practices. In many places, there is still a lack of sufficient coastal data to support sound management (Example “[São Tomé and Príncipe, Southern Atlantic Ocean: Small Fishermen Communities at Risk](#)”). A proactive attitude, emphasizing the collection and scientific analysis of coastal data, will improve policy design and decision making in the future. This is necessary also with a view towards coastal adaptation to climate change.

Engineered Versus Ecological Design

Civil engineering solutions have been traditionally prominent in coastal management worldwide (see, for example, Pranzini

Coastal Management

Practices, Fig. 2 Coastal squeeze and disruption at the Dutch mainland coast between 1850 and 2000. Note the increase of build-up areas (red) in and around the dunes (yellow). Entrance piers to harbors of Rotterdam (bottom right) and Amsterdam (top right) can be seen

and Williams 2013). Such solutions, for example, those to counteract erosion and prevent flooding from the sea, use hard structures. Examples are groins, dikes, dams, breakwaters, and barriers. An increase in hardening and armoring of shorelines has been the result worldwide. At the same time, the ecological functions and dynamics of the natural system were overlooked or disregarded, and sometimes seriously destroyed. As a result, coastal biodiversity declined (see, for example, Rachel et al. 2016; Dethier et al. 2016).

In recent years, an important shift is seen from hard constructions to nature-based designs, where this seems a possible option. Such designs aim to make use of natural processes, materials, and elements that are present at a given location. This approach has been termed “building with nature” (Waterman 2008, 2010) or ecological engineering. Using this approach means that coastal managers aim to work “with” nature, rather than “against” it. This might be an option in many places with soft coasts, for example, beaches and dunes, but also wetlands, like mangroves and estuaries. In the long term, nature-based management might turn out to be more long lived and cost effective. It certainly increases system adaptability (for example, coastal adaptation to climate change) as well as biodiversity (Temmerman et al. 2013, Nat et al. 2016). Borsje et al. (2010) illustrate how ecological engineering can be used for coastal protection at different scales. From optimizing texture and structure of hard constructions in the intertidal zone on microscale to employing mussel and oyster beds on the meso-scale and using vegetation stands and landscape elements on the macro- and megascales.

The growing momentum for nature-based solutions is also illustrated by two recent publications (World Bank 2017 and Esteves 2014). The World Bank publication attempts to take a step towards standardized guidelines for all nature-based solutions. Five basic principles that came out of recent projects are discussed: (i) take a system-scale perspective; (ii) assess the risks and benefits of the full range of solutions; (iii) use standardized performance evaluations; (iv) integrate with ecosystem conservation and restoration, and (v) apply adaptive management.

Esteves (2014) explains the need for adaptation to nature/natural forces in coastal protection while shifting from hard engineering to nature-based designs. This implies so-called managed realignment. More room is given to habitat creation and coastal ecosystems with their intrinsic dynamics. Examples mainly come from Europe. In reality, one often sees a combination of hard and soft solutions. Along increasingly crowded shorelines, hard responses may be necessary, both politically and economically. A crucial point, however, is that those involved must recognize that their benefits may be short lived as climate change unfolds.

Examples of Management Practices

A limited number of examples of practices and “lessons learned” are selected to illustrate various methods of CM (Fig. 3). They give the reader a feeling for the opportunities for coastal management in the twenty-first century.

Coastal Management Practices, Fig. 3 Location of examples of management practices discussed in this entry. Bangladesh 1, Marshall Islands 2, Mekong Delta Vietnam 3, The Netherlands 4 and 6, São Tomé and Príncipe 5

In general, all the examples illustrate, be it in different contexts, aspects of the features of CM that are highlighted above. But in each example, some features stand out more than others. São Tomé and Príncipe (5) together with Marshall Islands (2) present a small-scale case in a developing cultural setting, scarce on data and coastal experience. Physical and hydrological modelings are tools used. The few field data were combined with desk studies. In the case of Marshall Islands, the emphasis is on a building with nature solution. In ST&P on stakeholder involvement, risk analysis and public acceptance of the results. Although still on a small scale and in early stage, this example shows the principle of risk and benefit assessment (World Bank 2017). Bangladesh (1) and Vietnam (3), as more developed countries, present large-scale examples with dense coastal populations, where building with nature can also be a more sustainable solution. It involves entire coastlines. Stable governance over time and a long-time undertaking are needed. The principle of Integration with ecosystem conservation and restoration (World Bank 2017) applies to these examples. The case of The Netherlands (4, 6) show what can be done in a developed setting with much data and a large coastal experience. Again, building with nature is a component, both at the coast and along rivers. Long-term monitoring, modeling, a proactive (government) approach and learning by doing are CM features here. The example also shows the principle of taking a system-scale perspective (in space as well as in time) (World Bank 2017).

Bangladesh, Northern Bay of Bengal Coast: A Low-Lying, Densely Populated and Vulnerable Delta

Almost the entire country of Bangladesh consists of one of the largest delta floodplains of the world, reaching more than 100 km inland. It presents very dynamic hydrological, morphological, and landscape-ecological characteristics. Three of

the world's largest rivers, the Ganges, the Brahmaputra, and the Meghna, together contribute huge volumes of water and sediment. About 80% of the country is covered with rivers and their floodplains. These rivers are the arteries for life, livelihoods, and economy. Water management in terms of quantity and flood protection is a very complex and challenging issue in Bangladesh. Proper management of water resources is essential for the future development of the country. The Bangladesh Delta Plan (General Economics Division, Bangladesh Planning Commission 2017, draft not for publication) is a guideline for such development. It stresses stable governance and a long time undertaking.

During the monsoon season of just 4 months, hundreds of millions of cubic meters of water flow through the country. More than 90% of this comes from countries upstream in the Himalayan highlands. During the dry season, human interference with the river system is wide spread, due to the requirements of agriculture. The upcoming impacts of climate change are affecting river flows, complicating river management to a large extent. Sea-level rise in combination with land subsidence already cause extensive low-lying areas to flood. In the near future, Bangladesh will face increased flood risks as well as challenges regarding water quality, droughts, and salinization and greater land subsidence.

In some areas, tidal pumping is affecting the downstream tracts of tidal rivers, clogging them with sediment, as polder dikes prevent the spreading of this sediment (Fig. 4). However, exactly this sediment can be used to increase the elevation of parts of the floodplain that have become isolated (by the polder dikes) from sediment supply for half a century by now.

A combined and coordinated management approach on water and sediment could provide a way out. Due to the extent of the floodplain and the prevailing natural conditions (mega-rivers loaded with sediment, monsoon flooding, drought, high tidal levels, effects of cyclones, dense population, the need for

Coastal Management

Practices, Fig. 4 Sediments choking a tidal river in Khulna District. The sediment can be utilized to increase the elevation of the low-lying areas behind the banks. (Photo: Bert van der Valk)

agriculture, and aquaculture production), this management approach needs long-term planning and adequate funding. Stable governance, without frequent changes, is a prime requirement. Proper water and sediment management, from a system-scale perspective, needs to be a key to this process. Temporarily opening up of polder dikes to allow controlled sediment transport into low-lying areas is one of these measures (Tidal River Management: see, for example, the Uttaran plan 2013).

In some areas, short-term measures can be training of shrimp farmers for better use of mangroves for the improvement of the natural conditions of their shrimp ponds, as well as for better yields and quality of shrimps. This involves sediment management. Long-term measures involve more drastic ways of “artificial” (re)distribution of delta sediment using the forces of nature.

Marshall Islands, Pacific Ocean: Survival Techniques for Atolls

The sustainability of human habitation of thousands of low-lying atoll islands is threatened. Threatened by sea-level rise, but more so by salinization of their fresh water resources due to wave-driven over wash (Storlazzi et al. 2018).

The Republic of the Marshall Islands consists of an atoll archipelago located in the central Pacific, stretching approximately 1000 by 1300 km. The archipelago consists of 29 atolls and 5 reef platforms. They are host to approximately 1200 islands with an average elevation of 2 m above mean sea level. Over 3/4 of the population is concentrated on the two atolls of Majuro and Kwajalein. These islands (size 10 resp. 16 km²) have low adaptive capacity. The adaptation costs are high, relative to the gross domestic product (GDP). Consequently, they are very vulnerable to natural hazards and to effects of climate change.

A coastal hazard assessment was made for the islands of Ebeye and Majuro (Giardino et al. 2018). The following

hazards were analyzed as part of a desk study: waves, storm surges, typhoons, and tsunamis. The direct impacts (inundation and coastal erosion) were evaluated, specifically for the island of Ebeye. The analysis was carried out for different return periods and expected climate change scenarios and sea-level rise. The hazard assessment was then used as a basis to carry out a coastal risk assessment, in which information on hazards was combined with information on exposure and vulnerability. The output from the risk assessment allows the determination of weak spots where adaptation measures may be required. A conceptual design and cost-estimate is presented for present or near future measures. The method is used to test the effectiveness of each of these measures, in achieving the predefined objective in terms of risk reduction. This is a very effective strategy for reducing the total investment costs and maximizing the future benefits of the interventions (Giardino et al. 2018).

Technical measures include: (i) dredging coral sand from the reef to raise the island’s level and to reclaim land for the extension of living space; (ii) construction of a rock revetment breakwater around the island to protect against over wash by ocean storm waves, and (iii) provision of construction materials (coral sand and gravel) to the island’s community. These measures will hold for other low-lying islands in general, of course focused on local requirements (Fig. 5).

Coral atolls have a very rich and vulnerable marine biodiversity. It should be safeguarded through special measures, in particular during dredging and reclamation activities. Special monitoring programs are required to monitor environmental changes before, during, and after the work has been completed.

Vietnam, Mekong Delta: Mangroves for Coastal Defense

In part of the Mekong Delta (Southern Vietnam), sedimentation still prevails near the estuarine inlets. But further inland, coastal erosion (due to natural and human-induced causes) is occurring. This erosion is anticipated to increase in the future

Coastal Management

Practices, Fig. 5 Supplementing sediment to Thinhadho Island (Maldives), setting a scenario for other low-lying islands in the world’s seas (Photo courtesy Van Oord, Richard Heerschap)

for several reasons: (i) the increasing number of dams in the Mekong River basin, capturing bed load as well as suspended sediments that will no longer reach the coast, (ii) the increasing human-induced land subsidence in the lower delta due to groundwater extraction for agriculture, aquaculture, and human consumption, and (iii) climate-change induced sea-level rise (IUCN 2011).

The decrease of the suspended solids content of the river and the decline of mangrove health, due to mangrove squeeze (Phan et al. 2015), are of particular impact. Coastal recession contributes to the loss of (mangrove) area, increases salt water intrusion and is detrimental for activities like agriculture and aquaculture and for coastal infrastructure. The best possible measure to mitigate coastal erosion is planting of mangroves in suitable (accretionary) areas, using the sediment entrapment and wave-attenuation properties of mangrove tree stands. Model studies confirm the applicability of this type of measure (Phan et al. 2015). Studies along degraded (and erosional) mangrove coasts have demonstrated the vulnerability of such coasts to almost any kind of human land-use other than nature oriented (Winterwerp et al. 2013).

Spalding et al. (2010) observed the role of mangroves in risk reduction: wind and swell waves are being reduced while passing through mangrove stands. The wider the mangrove belt, the stronger the attenuating effect. Sediment binding and fixation by mangrove roots is also important, especially over time. For an increase in coastal safety, mangrove stands should be recognized as valuable elements of coastal protection. They need to be incorporated in long-term coastal planning by all stakeholders. Phan et al. (2015) found an average critical width of 140 m for the southeastern and eastern Mekong Delta to sustain a healthy mangrove that attenuates wave energy.

New mangrove forestation is not an easy practice. It certainly implies more than simply planting the trees. Mangrove protection and restoration may be more effective, because ecological conditions are dynamic and very subtle. Mangrove stands may better recover in areas where they were growing

previously. This illustrates the principle of integration with ecosystem conservation and restoration (World Bank 2017). The costs for protection are far lower than those for new forestation. Natural mangrove forests are not very rich in species but have a high regeneration capacity. Use this capacity. In erosional areas, additional measures may be needed (keep sediments, plant actively). Green funds may be very helpful in financing combined projects for mixed purposes of mangrove recovery, (economic) livelihoods, and safety of the population.

The Netherlands, Southern North Sea Coast: “Building with Nature” in a Sandy Environment

The Netherlands present interesting recent examples of “building with nature” practices. They illustrate a system-scale perspective (World Bank 2017). They can be found in the south west along the North Sea coast (Fig. 6). Here, the coastal zone is narrow (just 0.2–0.5 km) with beaches and dunes that protect the low-lying hinterland (1–4 m below sea level). The area is very densely populated with glasshouse culture as main land-use. Large towns are The Hague and Rotterdam. This coast has been erosive for centuries. In medieval times, it was part of the estuary of the river Rhine and Meuse with a coastline extending some 1.5 km further seaward than today. Persistent coastal erosion is the reason why the present coast is so narrow. Since at least 200 years, various hard methods of coastal defense have been applied (dikes, groins). Two recent examples, using larger scale sand nourishment, show “building out into the sea” as a measure. They are the Sand Motor (www.dezandmotor.nl) and Spanjaards Dune.

The Sand Motor

The Sand Motor (www.dezandmotor.nl) is an innovative method for coastal protection, taking the system-scale of a whole coastal sector into account. It consists of a huge volume of sand (ca. 20 ml m³) and was constructed in 2011 (Fig. 6, middle). The original form was a hook-shaped peninsula, extending 1 km into the sea and 2 km alongshore.

Coastal Management Practices, Fig. 6 Left: The coast between The Hague and Hook of Holland (see inset for location). This coast is narrow and protects densely occupied hinterland, lying below sea level. Reflective white surfaces represent intensive glasshouse culture (Google

Image). Middle: the Sand Motor, 2013. Right: Spanjaards Dune, 2013. Black lines indicate the original alignment of the coast before construction. (Air photo courtesy Rijkswaterstaat)

Wind, waves, and currents are spreading the sand in a natural way, with the prevailing longshore current (mainly to the coastal sector northwards), thus reinforcing this coastline and creating a dynamic area for nature development and recreation. The Sand Motor has been gradually changing its form, diminishing in size, and will eventually fully merge with the original alignment of the coast. The large-scale Sand Motor nourishment will replenish the local sediment budget for a much longer time than the routineous smaller scale nourishments planned here and to the north. Nourishing a large volume in one go is supposed to be cheaper and better for the benthic ecology than repetitive smaller nourishments. The first evaluation report (Taal et al. 2016) concluded a.o. that the life span of the nourishment will possibly be twice as long as the 20 years that had been estimated by modeling before construction.

The Sand Motor is an integrated solution. It combines coastal defense through maintaining the sand budget on an erosional coast, scientific research, nature development, and recreation.

Spanjaards Dune

This dune area (35 ha) was constructed in front of the existing coast (Fig. 6, right) in 2008/2009, as compensation for the expected loss of valuable existing dune habitats nearby. The loss, mainly because of increasing deposition of traffic emissions, is due to the extension of the Port of Rotterdam with Maasvlakte 2 (van der Meulen et al. 2014). The existing dune habitats in question are protected under the EU Natura 2000 legislation and therefore had to be compensated (van der Meulen et al. 2015). The compensation was realized by constructing a whole entire new dune ecosystem that, over time, will develop into the compensation habitats. This approach illustrates the ecosystem-scale principle (World Bank 2017). The basic foundation of the new area is reclaimed from the shallow North Sea by shore face-, beach-, and dune nourishment (6 million m³). After the construction of this abiotic “ground plan,” natural processes (wind, rainfall, groundwater dynamics, and vegetation succession) have free play to shape the area further, developing it into the dune habitats that need to be compensated. These “target” habitats are calcareous, nutrient-poor dune marsh, and dry dune grassland. The marsh may take 5–10 years to complete but the grassland takes 15–20 years. Careful management, monitoring, and evaluation are needed to assess whether the desired development is indeed taking place and to adjust when necessary. Important questions for the monitoring are: (i) Is the eventual damage to existing dunes going to be as it was predicted? (cf. Royal Haskoning Nederland 2006); (ii) Is the quality of the new compensation area going to be enough to compensate for this damage?

Because of the EU obligation to compensate, this project also has a political dimension. It is a unique example of a one-

to-one field experiment (learning by doing) where politicians, engineers, ecologists, and managers work and learn together.

“Learning by doing” in building with nature is important because more experience is needed on ecosystem behavior (both physical as well as biological) to be able to apply this knowledge.

The compensation aspect is worth considering worldwide where ecosystem damage occurs as a result of (large) engineering projects, such as harbors.

São Tomé and Príncipe, Southern Atlantic Ocean: Small Fishermen Communities at Risk

The islands of São Tomé and Príncipe present an example of coastal management practices at a less developing and isolated location with hardly any available data. And also of how to involve the local population so that results are truly appreciated and accepted by the receivers.

The Democratic Republic of São Tomé and Príncipe (ST&P) comprises two main islands and four islets located at the equator, in the Gulf of Guinea, 350 km off the west coast of Africa. It is one of Africa’s smallest nations with a total area of 1000 km² and population of 166,000. Angolares villages are small fisherman’s communities built at the coast, often at very isolated locations (Fig. 7). They have since long suffered from coastal inundation and erosion. The flooding increased in recent years, possibly due to increased storm intensity and shifts in the rainy seasons that have begun to overlap with the storm season. Climate impacts have probably been further increased by offshore and beach sand mining. In view of its isolation, small size, and limited capacity, ST&P was given the least developed country (LCD) and small island developing state (SIDS) status. The island’s fishermen communities are considered highly vulnerable to climate change and sea-level rise. Between 2010 and 2012, possible adaptation options were studied. The focus was at the fishermen villages of Malanza, Praia Sundy, Ribera Alfonso, and Santa Catharina (https://www.researchgate.net/publication/266216911_Sao_Tome_and_Principe_Adaptation_to_Climate_Change-Climate_variability_and_hydrogeomorphological_study, UNESCO-IHE and Deltares 2011).

At first, a study design with stakeholder plan was made. Potential hazards were assessed by making a climate variability scenario analysis and a coastal hydrology, oceanography, and geomorphology survey and subsequent analysis. The hazard assessment formed the basis for the risk assessment, where information on hazards is combined with information on exposure and vulnerability. This resulted in a coastal communities adaptation plan and recommendations for National Government. Also, a social assessment was carried out and risk maps were made (Fig. 8).

The technical analysis was done with the help of simple bathymetric profiles, surveyed with an Echo sounder (from the shoreline to –20 m) and a digital

Coastal Management Practices, Fig. 7 Left: View on Praia Sundy from the boat. Right: Fishermen houses on the beach and on higher ground

Coastal Management

Practices, Fig. 8 Risk map of Malanza fishermen's village (2012). Risk factors are flooding from the sea, from the river and coastal erosion. Flooded areas were qualitatively defined with help of terrain elevation, river discharge data, and 1/50–100 years storm surge event with 80 cm sea level rise by the end of the century. Risk class 1 involves flooded by the river and the sea and with a large number of houses. Class 4 involves only flooded by the sea at sea level rise of 80 cm by 2100 with only a few houses

elevation model of the coastal zone, using “storm data” (<http://strm.csi.cgiar.org>) for sediment transport and storm erosion calculations. Climate data were obtained from open sources and modified to fit the local situation as much as possible.

During the participatory meetings, the risk zones in the villages were shown on aerial photos and people were asked to comment on it. Three-dimensional mapping was used as a tool to interact with the communities and to discuss the various risks and potential adaptation measures. Positive and negative sides of the measures were written down. In addition, people were asked in which way they could contribute to implementation of the measure. It was advised to

proceed with the implementation in steps, in order to evaluate the efficiency of the measurements. Long-term monitoring and a stable government are needed to improve CM at the islands.

Room for the River: Ecological Engineering in the Lower Reaches of the River Rhine

In 1993, and again in 1995, two near-flooding events occurred in the lower Rhine flood plain. As a precaution, many people were evacuated. This urged an integrated plan for the area to prevent flooding in the immediate and more distant future. Climate models predict that by 2100, the peak winter discharge of the Rhine will increase from 16,000 to

Coastal Management Practices, Fig. 9 Overview of the area through which peak river flows will be diverted, Nijmegen, Eastern Netherlands. The area to be flooded is designed to conduct floodwaters for some

time until river levels are back to normal. In the meantime, the temporarily flooded areas function as wetlands. (Photo: <http://www.ruimtevoordewaal.nl> (Johan Roerink/Aeropicture.nl))

18,000 m³/s (Delta Commission 2008). Appropriate legislation for drafting such a plan was quickly initiated and passed by the government. Measures were implemented shortly after. The program was called “Room for the River” (see [RfR brochure](#); Sijmons et al. 2017). Major storage areas for controlled flooding were allocated (and in some cases “depolderized,” which is the reverse of reclaiming land from a wetland) to temporarily accommodate excess water during the peak of river floods. By design, these areas will start to function when the water level in the river exceeds a given threshold. The storage areas have the shape of real river courses, parallel to the normal river bed (Fig. 9). Or they are situated in the lower reaches of the river, where previously reclaimed polders were handed back to the river to become flooded-storage area during high water. The added advantage of these measures is that deposited river aggregates (sand, clay, gravel) become available for ready use during the construction period. The areas-to-be-flooded are wetland nature areas when not needed (van Staveren et al. 2014). This is another example of “building with nature” in a delta.

The Future of Coastal Management

Coasts will become more and more engineered with the construction of cities, harbors, and other infrastructure, pushing away room for nature. More emphasis will be needed to put on compensation of damage to nature and on co-development with nature. The concept of Green Port development is an example. Older harbor areas can be subjected to Brown-field development but equally focused on using “building with nature” type of measures.

The major challenge for the future lies in proactive thinking and governance. This involves integration of solutions, collecting and exchange of sufficient data to evaluate and use for prediction, awareness, and stakeholder involvement. Physical planning should reflect all ideas about coastal management. When it comes to practical measures in the field, one should be aware when, where, and how traditional engineering designs can be combined with new nature-based designs. More experience with the latter in different coastal environments is needed, because, at an increasing rate, coasts will be used and at risk (Scheffers et al. 2012).

“Man uses nature for all kinds of purposes. That is quite all right as long as we realize that we depend on her” (Saeijs 2008, p. 113).

Acknowledgments We are very grateful to Dr. Stephen Olsen (Coastal Resources Centre, University of Rhode Island, USA) and Dr. Ad van der Spek (Deltares, Delft and Utrecht University, The Netherlands) for their support and valuable comments on earlier versions of this entry. Figure 3 was drawn by Hans van Bergem, Deltares.

Coastal Modeling

Honghai Li

Coastal and Hydraulics Laboratory, U.S. Army Engineer Research and Development Center, Vicksburg, MS, USA

Definition

Coastal Modeling includes physical modeling and mathematical modeling. Physical modeling is to build a replica of a coastal domain, use scale-down ocean and atmospheric forcing to drive the system and study physical processes in the system. Mathematical modeling is to use numerical methods to solve the mathematical equations for conservation of mass and momentum and to simulate waves, hydrodynamics, sediment transport, and morphology change in the coastal zone. Various coastal models provide coastal engineers and scientists an efficient tool for understanding coastal processes and for designing and managing coastal inlets, beaches, navigation channels, ports, and coastal structures.

Introduction

Coastal physical processes include waves, storms, tide, current, and sediment transport. These processes can cause shoreline and beach changes, coastal inundation, and damages to coastal structures and properties.

Coastal waves are generated in open oceans due to winds, storms, or seismic activities, which carry energy and propagate to coastal areas. As approaching coasts, water becomes shallow, waves interact with sea bed, current, shoreline, and coastal structures. Due to shoaling and refraction, wave height and direction will change. When encountering coastal structures, stronger processes like wave diffraction, reflection, breaking, run-up, and overtopping will occur.

Ocean tide induces the regular rise and fall of sea surface and is driven by the combined gravitational forces of Moon, Sun, and Earth. Tidal periods may range from a few hours to more than 10 years, while the main tidal components include diurnal and semi-diurnal periods. Associated with tidal changes in water surface elevation are the horizontal water movement and tidal current. The regular water ups and downs in coastal regions correspond to the convergence and divergence of tidal current, including the interaction between tidal current and shoreline geometry.

Ocean current is driven by two classes of natural forces (Pond and Pickard 1983). Primary forces include gravitational, wind, atmospheric pressure, and seismic forces, and secondary forces are Coriolis and friction forces. On the contrary, coastal circulation are mainly driven by tide, wind,

and density gradient. Depending upon the nature and the relative importance of forces, and geographical locations, coastal currents can be vertically uniform or varying with depth.

Storms generated in tropical oceans or in the polar regions move past coastal regions, induce water level rises and falls, and enhance coastal and estuarine circulation. Extreme water levels due to storms are storm surges, which, combined with storm winds and peak tides, may result in extensive coastal flooding, land recession, and massive loss of human lives and properties (Nummedal et al. 1980; Halverson and Rabenhorst 2013; Li et al. 2013a).

Coastal structures are built to protect coastal residents, shorefront properties, and infrastructure, to prevent shoreline erosion, and to improve environmental conditions for coastal community and ecosystems. These structures include seawalls, jetties, breakwaters, groins, weirs, culverts, and tidal gates.

The combination of physical forces acts on coastal systems and interacts with complex coastlines and coastal structures, which cause coastal sediment movement. Sediment transport processes in coastal zones include longshore and cross-shore sand migration due to wave action, navigation channel scouring and infilling, changes of beach face, coastal shoaling, and sandbar formation.

Accurate modeling of coastal physical processes is required in engineering studies for coastal inlets, shore protection, nearshore morphology evolution, harbor design and modification, navigation channel maintenance, and navigation reliability.

Physical modeling has been a powerful means used for coastal studies. With the fast development of computer technology and its cost efficiency, mathematical modeling has become more popular in the last couple of decades. In this write-up, coastal numerical modeling will be described in different aspects of coastal studies.

Wave Modeling

Waves possess energy and propagate towards shoreline. As approaching surf zones, waves will break and dissipate energy. In coastal regions, released wave energy is partially transferred into the driving force for coastal current and coastal sediment movement. Therefore, waves are the most important factor in studying coastal processes. Because of the complexity in wave generation and nearshore wave transformation, understanding and predicting wave action always present a challenge.

Among various approaches conducted for wave analysis, numerical wave modeling has been widely used in recent years. Two types of wave models have been developed and applied for solving scientific and engineering problems in

deep or coastal waters. The first type is phase-averaging wave models and the other is phase-resolving wave models.

Phase-averaging models calculate energy spectra of waves and are used to simulate waves in a large regional to global scale or a small coastal scale. Popular phase-averaging models include WAM (WAMDI Group 1988), WAVEWATCH III (Tolman 1991), SWAN (Booij et al. 1999), STWAVE (Smith et al. 2001), and CMS-Wave (Lin et al. 2008). The WAM and WAVEWATCH III models were developed to simulate wave generation for large scale, deep water applications. The National Centers for Environmental Prediction of NOAA operates the WAVEWATCH III model and provides wave analysis and forecast over global oceans and US coasts. Figure 1 shows a one-hour forecast snapshot of significant wave height on the East Coast of US. Three- to four-meter waves are observed in the open ocean and wave height is reduced to less than 0.5 m close to coastal areas. Waves propagate primarily in the wind direction, indicating that wind-waves are generated in open ocean areas.

While the SWAN and STWAVE models are used for wave generation in deep water and wave transformation in shallow water, the CMS-Wave model focuses on coastal wave processes, including diffraction, refraction, reflection, wave breaking and dissipation mechanisms, wave-current interaction, and wave generation and growth. In nearshore zones, wave energy dissipation and transfer due to bottom friction and depth-induced breaking is a great contributor to coastal currents, coastal sediment transport, and coastal structure impact. Four depth-limited breaking formula were examined and implemented in the CMS-Wave model (Lin et al. 2011). Figure 2 shows significant wave height distributions associated with different wave breaking criteria.

Phase-averaging models calculate wave generation and transformation by assuming uniformly distributed wave phases. In order to calculate wave propagation and wave processes more accurately, phase-resolving models focuses on detailed phase information. Because of the requirements for high temporal and spatial resolution,

Coastal Modeling, Fig. 1

WAVEWATCH III model product: one-hour forecast snapshot of significant wave height on the East Coast of US (http://polar.ncep.noaa.gov/waves/viewer.shtml?multi_1-latest-hs-US_eastcoast, accessed 11 July, 2017)

Coastal Modeling, Fig. 2

Calculated wave height distributions using (a) the extended Miche formula (Battjes 1972), (b) the extended Goda formula (Sakai et al. 1989), (c) the Battjes and Janssen formula (Battjes and Janssen 1978), and (d) the Chawla and Kirby formula (Chawla and Kirby 2002)

phase-resolving models are limited to the calculations of short-term processes in small-scale coastal domains. Such models include the mild-slope model (Berkhoff et al. 1982) and the Boussinesq model (Nwogu 1993). Demirebilek and Nwogu (2007) carried out Boussinesq model simulations to investigate wave energy transformation at a site along Guam's southeast coast near Ipan. The calculated wave propagation and corresponding significant wave height over the Ipan reef are shown in Fig. 3. The Boussinesq model simulations clearly display that wave shoaling and breaking processes and asymmetric bores over the reef.

Circulation Modeling

Shallow coastal areas experience strong tidal mixing, receive high wind energy input, and are very often categorized as vertical well-mixed water bodies. Therefore, two dimensional modeling is a common practice for coastal applications, in which the shallow water equations are derived by depth-averaged equations of conservation of mass and conservation of momentum in the Cartesian coordinate system as follows:

$$\frac{\partial D}{\partial t} + \frac{\partial Du}{\partial x} + \frac{\partial Dv}{\partial y} = 0 \quad (1)$$

Coastal Modeling, Fig. 3

(a) Wave propagation and
(b) significant wave height over
Ipan reef, Guam during a storm
event (Demirbilek and Nwogu
2007)

$$\begin{aligned} \frac{\partial Du}{\partial t} + \frac{\partial Du^2}{\partial x} + \frac{\partial Du v}{\partial y} + \frac{1}{2} g \frac{\partial D^2}{\partial x} - f D v \\ = \frac{\partial}{\partial x} \left(A_x \frac{\partial Du}{\partial x} \right) + \frac{\partial}{\partial y} \left(A_y \frac{\partial Du}{\partial y} \right) + (\tau_{sx} - \tau_{bx}) \end{aligned} \quad (2)$$

$$\begin{aligned} \frac{\partial Dv}{\partial t} + \frac{\partial Duv}{\partial x} + \frac{\partial Dv^2}{\partial y} + \frac{1}{2} g \frac{\partial D^2}{\partial y} + f D u \\ = \frac{\partial}{\partial x} \left(A_x \frac{\partial Dv}{\partial x} \right) + \frac{\partial}{\partial y} \left(A_y \frac{\partial Dv}{\partial y} \right) + (\tau_{sy} - \tau_{by}), \end{aligned} \quad (3)$$

where x and y are the horizontal coordinates; u and v are the horizontal velocity components in the x - and y -directions, respectively; D is the total water depth and is the sum of the still water depth, h , and the free surface deviation from the still water surface, η ; g is the gravitational acceleration; f is the Coriolis coefficient; A_x and A_y are the diffusion coefficients in the x - and y -directions, respectively; τ_{sx} and τ_{sy} are

the surface stress in the x - and y -directions, respectively; and τ_{bx} and τ_{by} are the bottom stress in the x - and y -directions, respectively.

Numerical solutions of water surface elevation and depth-averaged current are obtained in Eqs. (1), (2), and (3). Princeton Ocean Model (POM) is an early ocean circulation model (Blumberg and Mellor 1987), based on which the Estuarine Coastal Ocean Model (ECOM) was developed (Blumberg et al. 1992). Successful applications of POM and ECOM include many coastal and estuarine sites in US and around the world. ECOM is the core model of an operational forecast modeling system for the Mississippi Sound/Bight (Blumberg et al. 2002). Figure 4 shows the model forecasted surface current and salinity and the drifter trajectories. Considerable spatial variability in current and a persistent ocean eddy were exhibited in the figure.

The coastal modeling system (CMS) was developed at coastal and hydraulics laboratory of U.S. Army Engineer Research and Development Center. The CMS is an integrated suite of numerical models for simulating water surface

Coastal Modeling, Fig. 4

ECOM forecasted coastal current and salinity fields (Blumberg et al. 2002)

elevation, current, waves, sediment transport, and morphology change in coastal and inlet applications. This modeling system includes representation of relevant nearshore processes for practical applications of navigation channel performance and sediment management at coastal inlets and adjacent beaches. The CMS consists of a hydrodynamic and sediment transport model (CMS-Flow) and the previously mentioned spectral wave transformation model (CMS-Wave). CMS-Flow is a two-dimensional (2D) finite-volume model that solves Eqs. (1), (2), and (3) on a telescoping grid (Sánchez et al. 2011; Wu et al. 2011). Typical applications of the CMS include analyses of past and future navigation channel performance; wave, current, and wave-current interaction in channels and in the vicinity of navigation structures; and sediment management issues around coastal inlets and adjacent beaches.

The CMS was set up to conduct numerical modeling investigation adjacent to Merrimack Inlet, Newburyport, and nearshore in the vicinity of Salisbury Beach and Plum Island, Massachusetts (Li et al. 2014). Concerns at the site include beach erosion, shoreline retreat on Plum Island down-drift of and within the inlet, and reduced navigability of the inlet. Figure 5 shows the CMS configuration and calculated residual current around the inlet system.

Sediment Transport Modeling

Combined action of waves and current in nearshore areas causes significant shoreline change and sediment migration.

Simulating and understanding coastal sediment transport and morphodynamic processes is an important component in coastal modeling practice.

Sediment transport models simulate bedload, suspended load, or total-load (combined bedload and suspended load) transport of noncohesive and cohesive sediments. For muddy sediment bed (cohesive material), suspended load transport is the process to be considered; for sand sediment bed (noncohesive material), both bedload and suspended load transport processes have to be taken into account. As displayed below, the depth-averaged advection-diffusion equation is solved for sediment concentration and sediment flux in water column.

$$\begin{aligned} \frac{\partial DC}{\partial t} + \frac{\partial CDu}{\partial x} + \frac{\partial CDv}{\partial y} = & \frac{\partial}{\partial x} \left(K_x D \frac{\partial C}{\partial x} \right) \\ & + \frac{\partial}{\partial y} \left(K_y D \frac{\partial C}{\partial y} \right) \\ & + (E_b - D_b) \end{aligned} \quad (4)$$

where C is the depth-averaged sediment concentration; K_x and K_y are the diffusion coefficients in the x - and y -directions, respectively; and E_b and D_b are the erosion and deposition rates, respectively. The bedload transport in noncohesive sediment or in mixed cohesive and noncohesive sediment calculations have been obtained by researchers using empirical formulas in laboratory experiments (van Rijn 1984, 1993; Watanabe 1987; Soulsby 1997; Camenen and Larson 2005).

Coastal Modeling, Fig. 5 (a) The CMS telescoping grid and (b) bathymetry at Plum Island Sound and Merrimack Inlet. (c) Calculated residual current for January 2011 (Li et al. 2014)

In sediment transport models, the advection-diffusion equation and various transport formulas are used to calculate total load sediment transport. Once transport rates are determined, depth change (bed elevation change) can be calculated by the sediment continuity equation,

$$(1 - p) \frac{\partial z_b}{\partial t} = \frac{\partial q_{t,x}}{\partial x} + \frac{\partial q_{t,y}}{\partial y} \quad (5)$$

where p is the porosity of sediment; z_b is the bed elevation; and $q_{t,x}$ and $q_{t,y}$ are the total load sediment transport rates in the x - and y -directions, respectively.

CMS-Flow in the CMS has three noncohesive sediment transport models which differ mainly in the

assumption of the local equilibrium transport for the bed and suspended loads (Buttolph et al. 2006; Sánchez and Wu 2011). CMS-Flow can simulate any number of sediment size fractions, the interactions between size fractions, bed sorting and layering, and morphology change. The sediment transport model also includes processes such as avalanching, nonerodible surfaces (hard bottom), and bed slope effects.

Grays Harbor estuary is located on the southern coast of Washington, USA. A large natural inlet on the west connects the harbor to the Pacific Ocean through a deep draft navigation channel. In recent years, the elongation of Damon Point, a spit on the northeast portion of the harbor entrance, has caused the channel thalweg to migrate. The purposes of the

Coastal Modeling, Fig. 6

Calculated sediment transport pathways and net total-load sediment transport rates (Li et al. 2013b)

CMS development for the Grays Harbor estuary are to evaluate potential shoaling in the navigation channel and its possible link with the growth of the Damon Point spit and to investigate physical consequences of the Damon Spit encroachment and associated channel migration. Figure 6 shows the conceptual sediment transport pathways and the calculated net total-load sediment transport rates around the inlet system (Li et al. 2013b).

Delft3D-SED is the sediment transport and morphology module in Delft3D modeling suite (DELFT HYDRAULICS 2006). For noncohesive sediment (sand), both bedload and suspended load transport are calculated; for cohesive sediment (mud), suspended load transport is calculated with the incorporation of flocculation and consolidation processes.

Sloff et al. (2012) developed a numerical morphological model at the mouth of Rhine and Meuse Rivers, which is an

extension of the existing Delft3D model of the Rhine branches in the North and the West of the Netherlands. The modeling study is to improve the understanding of hydrodynamics and morphodynamics in this estuarine system and help develop local sediment management strategies in response to flow pattern changes and erosion variations due to the construction of the Deltaworks.

The morphological model was implemented by specifying fractions of both cohesive and noncohesive sediments from silt to coarse sand. Figure 7 shows the calculated suspended sediment transport rates of silt and sand material. As found in the study, Sloff et al. (2012) indicated that suspended load transport is the dominant process comparing with bedload transport in the estuarine system. Therefore, bed elevation change shown in Figure 8 is well corresponding to the distribution of sediment transport rates in Fig. 7.

Coastal Modeling, Fig. 7 Cohesive and noncohesive suspended sediment transport (Sloff et al. 2012)

Coastal Modeling, Fig. 8 Bed elevation change. The warm color represents accretion and the cold color erosion (Sloff et al. 2012)

Shoreline Change Modeling

Coastal engineering practice and regional sediment management require understanding of beach evolution and shoreline change, and numerical modeling of dominant sediment transport and morphologic evolution processes in coastal littoral zones.

GENESIS, GENeralized model for SIMulating Shoreline change, is such a numerical model to calculate longshore sand transport and simulate shoreline change in response to wave action (Hanson and Kraus 1989). The equation of the model is governed by conservation of sediment mass under assumptions of constant beach profile shape, impact of longshore sediment transport, and existence of a long-term trend in shoreline change et al. and is described as below:

$$\frac{\partial y}{\partial t} + \frac{1}{(D_B + D_C)} \left(\frac{\partial Q}{\partial x} - q \right) = 0 \quad (6)$$

where x is the alongshore coordinate; y is the cross shore coordinate, representing the shoreline position; D_B and D_C are the newly formed berm height and the closure depth, respectively, relative to a vertical datum; Q is the alongshore sand transport rate parallel to the x -coordinate; and q is the

sand input in the y -direction. The solution of shoreline position obtained from Eq. (6) is interpreted in Fig. 9.

As a one-dimensional shoreline change model, GENESIS was designed to simulate shoreline/beach evolution over a period from months to several years. With wave input as the major driving forcing, the model can be used to assist coastal engineering projects, such as coastal structure design and evaluations, beach nourishment, and berm placement. While GENESIS focuses on shoreline change studies in a local spatial scale (project dimension) and a relatively short temporal scale of several year, the Cascade shoreline change model was developed to simulate alongshore sediment transport and morphologic evolution of shoreline in a large regional scale and a long-term temporal scale. The Cascade model can cover a coastal domain up to hundreds of kilometers and simulation periods can be extended to more than a century to address long-term influence of natural processes on coastal changes (Larson et al. 2006).

Based on theoretical framework of GENESIS and capabilities of Cascade in calculating large spatial scale longshore transport, morphological change, and interaction between coastal processes and coastal structures (inlets) over a long period of time, GENCADE was developed (Frey et al. 2012).

Coastal Modeling, Fig. 9

(a) Side view and (b) Plan view of solution procedure of Eq. (6) (Frey et al. 2012).

Figure 10 shows a test case with a single inlet along a straight shoreline. Under constant wave forcing with the assumption of equilibrium morphological elements, the simulation results display the shoreline response of updrift sediment accumulation and downdrift erosion.

Coastal change and shoreline evolution have been greatly influenced by coastal flooding due to storm conditions and could be impacted by future sea level rise. Driven by waves and water levels, SBEACH, the Storm Induced BEACH model, is a storm-scale numerical model for simulating beach profile change, the formation and movement of longshore bars, troughs, and berms, and dunes (Larson and Kraus 1989). By neglecting longshore transport components, beach profile change is obtained from the calculation of cross-shore transport rate and the mass conservation equation along cross-shore transects.

SBEACH can be applied to determine the fate of proposed beach fill alternatives under storm conditions and to compare the performance of different beach fill cross-sectional designs, and to predict volumetric overtopping rates for

catastrophic events in open coasts. King et al. (2011) applied the model to evaluate beach profile and shoreline change in response to storm surges along Wallops Island, Virginia. As shown in Fig. 11, the hurricane induced surge had caused berm and dune erosion.

As a one-dimensional numerical model, GENCADE simulates shoreline change and SBEACH calculates cross-shore profile change under various wave forcing. Both models can predict beach profile change, berm, and dune migration in different spatial and temporal scales but with limitations of the assumptions of equilibrium sediment transport and breaking of short-period waves. XBeach is a two-dimensional time dependent swash and surf zone model (Roelvink et al. 2009). This model solves coupled short wave energy, flow, sediment transport, and bed level change equations for cross-shore and longshore hydrodynamic and morphodynamic processes on a spatial scale of kilometers and a temporal scale of storms.

Coastal physical processes included in the model are wave transformation, wave setup and overwashing, longshore, and

hurricane (King et al. 2011)

cross-shore hydrodynamics, bed load and suspended load sediment transport, dune erosion, etc. McCall et al. (2010) set up the XBeach model to calculate morphological change and coastal inundation due to Hurricane Ivan at Santa Rosa Island, Florida. The simulation period is 36 h. Figure 12 shows the comparison between the calculated morphological changes at the end of the simulation and the LIDAR measurements. The figure clearly indicated that the storm surge and wave action resulted in the dune inundation and sediment

transport over the barrier islands, and two washover fans were created in the back barrier bay.

Coastal Structure Modeling

Various coastal engineering structures are built to protect shoreline, harbors, and navigation waterways, which include rubble mounds, weirs, culverts, tidal gates, et al. (Fig. 13). Since these

Implementation of coastal structures in coastal modeling

structures are a significant component in controlling hydrodynamics and sediment transport in the coastal zone, it is important for a coastal numerical model to properly represent them and to simulate their effects. In coastal models, structure effects are usually treated as the obstructions in flow fields and are represented as energy loss in the governing equations. The term has the form of a friction term with an empirical dimensionless coefficient. Depending on the type of structures, the energy loss can be evaluated by a linear or a nonlinear form.

Rubble mound structures are typically used as seawalls, groins, breakwaters, and jetties. The design of rubble mound structures often consists of a core of small- to medium-size rock or riprap covered with larger rock or riprap to armor against wave energy. In coastal modeling, it is reasonable to assume that the flow through these structures is negligible, since the flow is controlled through laminar flow through small pores, and they are therefore often represented as solid structures, impermeable to both flow and sediment transport. However, some designs may implement larger diameter riprap in the core, and the resulting structure can be sufficiently porous to allow flow across the structure. The flow resistance in these structures can consist of both laminar and turbulent components; the pore space can provide significant storage for sediment and act as a sediment trap. Fine, grain-sized sediments may pass through the structure (Li et al. 2015).

The Forchheimer (1901) equation describes unidirectional flow in porous media, in which the laminar (linear) and turbulent (nonlinear) components of flow resistance are represented. The numerical implementation of the formulation in the CMS is to incorporate the resistance equation into the governing equations, representing the drag force of the rubble mounds. Both the linear and nonlinear coefficients in the equation are determined using data from studies by Sidiropoulou et al. (2007).

Weirs are common coastal structures typically used in weir jetties or in wetlands to control discharges, provide flood control, act as salinity barriers, and optimally distribute freshwater to manage salinity regimes and sedimentation rates and deposition patterns. Weirs are also used in inland streams to increase navigation channel depth, collect water runoff from agricultural fields, control sedimentation, and stabilize channel morphology.

Two approaches are developed to implement weir structures in the CMS model. The first approach is based on the standard weir equation for either sharp-crested or broad-crested weirs, with a foundation in Bernoulli's equation. The second approach is to add local resistance force over a weir structure in the momentum equations.

In coastal applications of culverts, the culverts often connect open water bodies of similar water surface elevation with two coupled locations, for instance, to enhance flushing or provide controlled flow through levees or causeways. Therefore, the implementation of culverts assumes subcritical flow

conditions. In the CMS, the implementation of culverts is based on equations developed by Bodhaine (1982).

Gates along with levees, dikes, and roadways are often used in tidal areas to control the water flow. They can increase flushing, improve water quality and also provide passage for fish and other aquatic animals to coastal lagoons and bays. Some gates may be self-regulating (controlled by water level) and some are manually operated according to certain schedules to meet the requirements of flood control, navigation, water quality management, and aquatic ecosystem rehabilitation. Figures 4, 5, 6 and 7 show some typical weirs, tide gates, and culverts used in coastal engineering and other areas.

Similar to the treatment of weirs, two approaches are used to simulate gate functions in the CMS model. The first approach determines the underflow through gates using the orifice flow equation. The second approach adds the local resistance force due to gates in the momentum equations.

Summary

Coastal modeling covers a wide variety of coastal, estuarine, and riverine processes that include wave dynamics, coastal circulation, storm surge and coastal flooding, tidal hydraulics and flushing, sediment transport, and shoreline change and beach erosion. Proper representation of coastal physical processes in physical or numerical models will greatly assist coastal engineering design and improve coastal management.

Presently, as mentioned early, many coastal models are available for applications. However, not one model fits every single situation and it depends on the discretion of coastal modelers (engineers and scientists) to select the right model to apply for a specific site to solve a specific problem.

Possibility of loss

Definition

Coastal Risk is defined as the ecological, social, economical, functional, and cultural damages possibly caused to coastal areas due to their geographical location. The risk is conditioned by two components: kind of menace and vulnerability. For that reason, coastal risk means that the coastal area is exposed to the possibility of loss. To know the risks a specific coastal area is exposed to, the possible consequences of a natural or anthropic event impact, and the probabilities of some kind of danger or threat to that area, have to be previously assessed.

Introduction

Large urbanized areas have been founded at coastal zones due to the growing number of population in different countries.

According to Shankardass (Spokesperson of the United Nations Program for Human Settlements (Habitat)), “Coastal cities grow at a rate of 20% faster than others; having also 10–15% greater number of population density.” Coastal cities and small insular States concentrate a population rate of about 643 million inhabitants, representing the 10% of the world population; being, therefore, all those people in great risk of the consequences of the climate change (GN 2007; IPCC 2014).

Vulnerabilities and risks of coastal population have lately increased, not only because of the changes in climate conditions, as the continuous sea-level rise, but also because of the great number of natural catastrophes and the creation of nonplanned urban areas (Cardona 2001; Milanés et al. 2017a). Analysis of the risks and vulnerabilities of urban coastal zones might give a solution to such complex problems.

In the present chapter, a critical review about various methodological frameworks used for establishing coastal risks is carried out. The following five aspects were taken into account for the analysis: (1) kinds of actual risks; (2) disciplinary approaches about risks; (3) relationship among coastal risk–menace–vulnerability; (4) current tools for coastal risk assessment; and (5) coastal risk management.

Kinds of Risks

The risk concept and associated terminology have varied not only throughout time, but also as a consequence of the different disciplinary approaches used (Cardona 2001). Up to the present, different kinds of risks have been studied from the theoretical and scientific points of view, such as: *urban risk* (Allen et al. 2017; Herslund et al. 2016; Milanés and Pacheco 2011; Bull-Kamanga et al. 2003); *urban environmental risk* (Lavell 2009a); *nuclear risk* (EPM 2010; GE 2009); *economical risk* (Mascareñas 2008); *marine or fishing risk* (Rezaee et al. 2016; Shahrabi and Pelot 2007; Wu et al. 2005); *geological risk* (Milanés et al. 2017a); *earthquake risk* (Guasch et al. 2008; Soloviev 1978); *coastal risk* (Milanés et al. 2017b; Zanuttigh et al. 2015; Botero and Milanés 2015; Milanés 2014; Bárcena et al. 2012; Gornitz et al. 1994), among others.

Some professionals working on themes related to disasters, use the term risk with only one concept, without making reference to the particularities involved in that term. For effective risk management, it is very important to know the differences among the various kinds of risks and corresponding variables.

Coastal risk has also been defined as “Expected damages in case of one or various kinds of menaces, no matter the origin, having the probabilities of affecting at a specific time and place, one or several vulnerable elements located within the coastal zone boundaries” (Milanés 2014; Milanés et al.

2015a). The variable called “geographical space” and the specific coastal zone characteristics are comprised in the previous concept, which needs essential knowledge about the territorial coastal boundaries object of analysis to be carried out into practice.

Following the previously mentioned concept, some nations take into account a narrow zone between land and sea for establishing coastal boundaries (MMA 2001; GORC 2000; Steer et al. 1997). However, some authors and coastal polices follow arbitrary distances to establish coastal boundaries (Henríquez et al. 2011; Abogado and Mendez 2003; GORC 2000). A new method, on the other hand, was designed for that task following differentiated integral and integrated criteria with the aim of proposing new programs for integrated management, planning and ordering of coastal zones (Milanés et al. 2017b). In all cases, the vulnerable elements to coastal risk, such as: housing, social buildings, infrastructure networks, economical goods, ecosystems, biodiversity, among others, have to be preventively assessed against different menaces to decrease damages, manage the risks, and increase resilience to the threat.

Approaches and Evolution of Coastal Risk

At present, great advances have been achieved regarding risks; however, any of the approaches followed by different disciplines have proposed a consistent and coherent theory about the disaster approach (Cardona 2001). The present climate-change effects, gradual sea-level rise, saline intrusion, erosion processes, and loss of coastal ecosystems have led to new studies, methodologies, and projects for analyzing coastal risk following an integrated, multi-transdisciplinary approach. Table 1 shows different disciplinary approaches about risk, as well as their characteristics and evolution.

Relationship Among Coastal Risk–Menace–Vulnerability

The concept of risk continues being misunderstood by some professionals, since the terms threat or danger are also equally used when making reference to risk (Cardona 2001). The term risk really means the possibility of people or systems of undergoing some kind of damage when exposed to a natural or anthropic phenomenon at a specific time period and place. The risk is a consequence of the mutual conditioning between threat and vulnerability and depends not only on social factors, but also on natural factors.

Identification of threats constitutes an essential component in studies about coastal risks because of the importance of knowing the probabilities of occurrence of a natural or

anthropic event of a specific magnitude at a particular geographical zone and time (Milanés 2014). Threats might occur at recurrent time periods, meaning the intervals of time of an event repetition. Events of great magnitudes generally have long recurrent time periods. Threats to people or territories depend on the following factors: event magnitude, frequency of occurrence, time duration, extent, speed, and particular space to be affected (Botero and Milanés 2015).

In some countries, e.g., in Cuba, the term danger is used as a synonym of threat (CITMA 2005; Cardona 2003; Lavell 2009a; DCC 2012). Some authors, like Milanés (2014), however, use those two terms differently, defining danger as any kind of natural or anthropic event affecting a particular territorial area, and considering the danger to become a threat when the event has the possibility of affecting one or more vulnerable elements, e.g., people, economic, and social goods, among others. Furthermore, the threat becomes a risk, coastal or not, when the previously mentioned factors coincide at a specific place causing social, environmental, and economic damages. A risk becomes coastal risk when the damages to people and territories are caused by the interaction between land and sea.

According to the origin and possibility of prediction, threats to insular or coastal regions are classified as follows: natural menaces, technological threats, and sanitary threats (Botero and Milanés 2015). For a threat to become a risk, it is necessary a scenario of vulnerability, meaning the presence of elements with probabilities of undergoing some kind of damage caused by a natural or anthropic event.

Vulnerability stands out at the urban coastal context as a relevant risk element. The economic, political, social, and environmental realities of every country have to be taken into account when studying coastal risks. Analysis of vulnerabilities is the starting point for getting knowledge about risks (Batista Matos 2006). The term vulnerability and its corresponding categories have been analyzed following various approaches, in correspondence with the institutions responsible of their assessment. For that reason, specific studies about the following categories or vulnerabilities have been done: urban vulnerability (Rosales 2004; Lavell 2009a; Milanés and Pacheco 2011; Herslund et al. 2016) and seismic vulnerability (Guasch et al. 2008; Milanés et al. 2015b), carrying this last category the analysis of social and physical vulnerabilities (Cardona 2003; Batista Matos 2006; CITMA 2005; Milanés 2014; Milanés et al. 2015b). Structural and Nonstructural vulnerabilities are included in studies about physical vulnerability, also called functional vulnerability by some specialists (CITMA 2005; Milanés et al. 2015b). For other authors, functional vulnerability is the same as institutional or political vulnerability (Botero and Milanés 2015; Milanés et al. 2017a). However, all the categories of vulnerabilities previously mentioned differ in behavior and results depending on the variables and contexts used for the analysis.

Coastal Risk, Table 1 Different approaches about Risk and Evolution to the Integrated Coastal Risk Approach (Source: Modified from Cardona 2001)

Disciplinary approaches	Characteristics and evolution
Natural sciences	Study of severe natural phenomena, (e.g., floods, landslides, earthquakes, hurricanes, tsunamis, volcanic eruptions)
	Object of study by different specialists, like geologists, seismologists, geophysicists, meteorologists, hydrologists, biologists, among others
	Reduced view, or partial approach about risk, considering the threat only “part” of the risk (Cardona 2001)
	Analysis of geodynamic and hydrometeorological menaces, considered remarkable contributions to risk assessment
	Great technological advances, although prediction of events, like earthquakes and tsunamis, is still very difficult
	Use of advanced technological systems, like sensors, for alerting and warning about intense events (e.g., hurricanes, floods, tsunamis, and volcanic eruptions) at real time (Cardona 2001)
Applied Sciences	Use in engineering and “hard” sciences
	Special attention to the physical properties of systems with possibilities of being damaged, or technologically destroyed by external phenomena (Cardona 2001)
	Concept of vulnerability incorporated from the disaster and modeling perspectives; use of probabilistic methods (UNDRO 1979)
	Recognition of the importance of analyzing threats and elements exposed to damage, including vulnerabilities, e.g., people and systems (Milanés et al. 2017a, b)
	Use in different disciplines, like geography, physical, urban or territorial planning, economy, environmental management, among others
	Use focused on the event effects associated to the threat, and not only on the event
	Restrictive view of the social, cultural, economical, and political aspects in assessing vulnerabilities and risks (Cardona 2001)
Technical sciences	Design and use of geographical information systems for the first time to draw maps with zones of danger or menaces in relation to the areas of influence of natural phenomena (Maskrey 1998)
	Use of specific and differentiated studies and methodologies to analyze the different kinds of risks
	Use of matrixes of damages to relate the phenomenon intensity with the damages caused (Soloviev 1978)
	Assessment of scenarios for potential losses, e.g., earthquakes in urban areas
	Use of decision-making processes for territorial ordering and physical planning
Social sciences	Risks estimated by analysis, or empirical information of the menace probabilistic modeling and possible damages (Cardona 2001)
	Study of people’s individual and collective reactions and perceptions toward risks (Mileti 1996; Drabek 1986)
	Study of the inhabitants’ reactions or responses to general emergencies, not only to risks (Cardona 2001)
	Analysis of the social character of vulnerabilities, not only the physic-potential damages, or demographic aspects
	Assessment of vulnerabilities, making reference to the inhabitants’ ability to respond and recover by themselves after an event impact (Westgate and O’Keefe 1976)
	Analysis of social factors, like fragility of family economy, absence of basic social services, lack of accesses to properties and credits, presence of ethnical, political, or other kinds of discrimination, high rate of illiteracy, lack of educational centers, among others (Maskrey 1994; Lavell 1996; Cardona 1996, 2001; Wilches-Chaux 1989; Mansilla 1996)
	Prevention and reduction used to decrease the pressure of social factors from global to local levels. Therefore, risk mitigation is directly involved in security conditions, dynamic pressures, and in other factors of influence (Wisner 1993; Cannon 1994; Blaikie et al. 1996; Cardona 2001)
	Risk conceived as something imaginary; thus, individual and collective perceptions, attitudes, and motivations vary according to the corresponding contexts (Johnson and Covello 1987, 2012; Slovic 1992; Luhmann 1993; Maskrey 1994; Adams 1995; Muñoz-Carmona 1997)
	Environmental impact and potential physical damages considered no essential when estimating risks (Cardona 2001)
Holistic approach	Integration of all disciplines
	Not only the expected physical damages, victims, or equivalent economical losses taken into account to estimate risks, but also the social, organizational, and functional factors related to the communities’ development (Cardona 2001)

(continued)

Coastal Risk, Table 1 (continued)

Disciplinary approaches	Characteristics and evolution
Integrated, multimethodological, and transdisciplinary approach	Dialogue among specialists of different sciences
	Interaction of different disciplines in relation to approaches, categories, and specialties (Milanés et al. 2017b)
	Respect for specialists' knowledge and multiple opinions when expressing different perspectives
	Unity of relationships, reciprocal actions, and interpretations of the different disciplines, keeping always their limits
	Search for unity of factors concerning opinions, methods, and languages
	Understanding the ways of dealing with flood risk management, or coastal risk interventions according to the physical, conceptual, and organizational borders (Nicholls et al. 1999; Bracken et al. 2016)
	Addition of multidisciplinary perspectives for integrated management of coastal risk and integrated management of coastal zones due to their essential link (Milanés et al. 2015a; Botero and Milanés 2015)
	Coastal risk, like flood risk, is considered an unavoidable and significant economic and social challenge to communities all over the world; therefore, the use of progressive and holistic approaches is necessary for adaptable management (O'Hare et al. 2016)
	The multidimensional nature of the assessment approach allows integration of at scale-information about cities, communities, and houses. This approach is novel in leading assessments about physical, social, institutional, and economic themes, as well as in understanding the ways of interaction among the underlying processes (Herslund et al. 2016)

Several definitions for the term vulnerability have been found in the bibliography reviewed (Cardona 2001, 2003; Batista Matos 2006; Lavell 2009a, b; Ruiz Rivera 2012; Guasch et al. 2008; Milanés 2014; Milanés et al. 2015a, 2017a), although two issues are analyzed in all of them: (1) probability of the territory exposed to risks of undergoing damages in case of threats and (2) preparation of the territory to face threats.

Current Tools Used for Coastal Risk Assessment

At present, various methodologies and tools are being used for determining coastal risks before the occurrence of natural threats or other kinds of danger (ICAM 2009; EMNDC 2005; AMA 2014a, b; Botero and Milanés 2015; Botero et al. 2017; Milanés et al. 2017b). Additionally, those tools are very helpful for taking preventive actions in order to avoid disasters, give quick responses, identify vulnerabilities, and calculate possible risks. Table 2 shows the positive results of coastal risk management when some current methods were validated at four coastal geographical regions of North America, Central America, South America, and of the Caribbean Islands (see Table 2).

Structural, nonstructural, functional, social, ecological, and economical vulnerabilities are all assessed in the three methods currently object of analysis in Cuba (CITMA 2005; EMNDC 2005; AMA 2014a, b). To calculate coastal risks, all those six different kinds of vulnerabilities are taken into account to get total vulnerability. Maps of danger, vulnerability, and risks are constantly drawn throughout all stages of the methodological tools, which require active participation of

experts, including scientists, technicians and decision-makers for their analysis and application. During validation of the Cuban tools in some of the Caribbean Islands, permanent presence of members of “Estado Mayor Nacional de la Defensa Civil” was really outstanding.

Coastal Risk Management

Managing coastal risk means analyzing, identifying, characterizing, and studying the different coastal menaces with possibilities of occurring at a given time (Milanés 2014). This kind of management requires a whole process of interinstitutional and multidisciplinary negotiations, and is supported by strategies, politics, and actions directed to prevent disasters and favor effective planning of coastal territory. Coastal risk management is also aimed to avoid or reduce an event impact and the consequences to the society of the dangers caused by the threats. Additionally, the threat magnitude, intensity, frequency, duration, repercussion on human life, economy, and on other social activities are equally taken into account for coastal risk management; procedure expected to have the following results:

1. Identification of different kinds of threat scenarios, being floods, tsunamis, storm surge, hurricane, landslide, sea-level rise, among others, the most frequently predictable coastal risks. Constant assessment during the hurricane season is extremely important for Caribbean countries because of the great impact tropical cyclones cause on shallow seas and lowland coasts (see Fig. 1a–c).

Coastal Risk, Table 2 Some international current tools used for coastal risk assessment

Tools	Objectives	Extent and work scales	Steps
Guide for assessing risk management using ICAM framework (ICAM 2009)	To facilitate practical and realistic range-risk assessment by the States Members	Procedures directed to assess probabilities of coastal risks according to the event location, frequency, magnitude, and possible factors influencing on magnitude modification	Introduction
	To give reachable and sustainable strategies	Risk assessment or local physiographic factors to know boundaries in potential risk of undergoing an event impact; thus, authorities can be alerted about priorities to mitigate risks	ICAM context
	To develop people's resilience to emergency situations in coastal communities	Changes in levels of vulnerability throughout time, e.g., environmental changes and those in coastal urban zones	Risk description
	To reduce or mitigate risks	Both risk and vulnerability assessment, indicate the policy and decision-making processes to follow	Identifying and quantifying risks
		The geographical scale of vulnerability depends on the resolution and extent of the assigned coastal management area in the ICAM process, called "macro scale" for the regional level, and "micro scale" for the local level	Vulnerability calculation Risk assessment Increasing awareness and risk arrangement Risk mitigation
Methodology for studies about danger, vulnerability, and risk of disasters by heavy rain and floods (AMA 2014a)	To calculate danger for different return periods	Analysis and evaluation of hydrographic basins, giving the results to the corresponding Province, Municipality, or Popular Council	Danger calculation:
	To mark dangerous zones on cartographic maps using geographical information systems	Work scale at 1:25,000, or higher	Identification of zones prone to flooding
	To identify all elements exposed to risk, calculate vulnerabilities and estimate risks using geographical information systems		Calculation of danger intensity and return periods Vulnerability calculation Risk estimation
Methodology for studies about danger, vulnerability, and risk of disasters by sea floods (AMA 2014b)	To calculate danger for different return periods	Identification of vulnerabilities and risks of elements exposed to several scenarios of danger	Calculation of danger by coastal floods:
	To mark dangerous zones on cartographic maps using geographical information systems	Presentation of results to the corresponding Province, Municipality, and Popular Council	Numerical modeling of surge
	To identify all elements exposed to risk, calculate vulnerabilities, and estimate risks using geographical information systems	Work scale at 1:25,000, or higher in case of detailed studies	Numerical modeling of waves
	To analyze and compare risk of every Province, Municipality, and Popular Council using the cartographic maps drawn by geographical information systems		Vulnerability calculation
	To do technical reports using the cartographic maps of every unit of analysis		Risk estimation

(continued)

Coastal Risk, Table 2 (continued)

Tools	Objectives	Extent and work scales	Steps
Methodology for studies about danger, vulnerability, and risk of disasters by intense wind (EMNDC 2005)	To calculate danger for different return periods	Use of the existing information and studies to work at every Popular Council. Presentation of results to different levels: Province, Municipality, and Popular Council (PC)	Danger calculation using:
	To identify elements exposed to danger, calculate vulnerabilities, and estimate risks using geographical information systems	Work scale at 1:25,000, or higher	The climate variable
	To draw cartographic maps marking areas of vulnerability and risks		Characteristics of the observational series
			Statistical modeling
			Vulnerability calculation
			Risk estimation
Methodology for formulating marine–coastal indicators associated to risk management (Botero and Milanés 2015; Botero et al. 2017)	To use the four marine–coastal indicators and corresponding sub-indicators for calculating interaction between governmental actions and coastal risk management	Use of methodological files with the four designed indicators	Enough knowledge about risks
		Work done at municipal coastal zones	Measures for risk mitigation
		Assessment of scenarios includes coastal particularities and variables associated to integrated coastal management	Preparation of institutional responses in case of emergencies
			Interinstitutional coordination and cooperation
Procedure used in four general processes for risk management and disaster mitigation (Milanés et al. 2017b)	To identify and diagnose different kinds of coastal risks	Holistic character	Four general processes to follow:
	To define future actions for improving present situations and introducing result analysis based on the principle of continuous improvement	Continuous assessment of various kinds of risks to reduce vulnerabilities in case of disasters	Diagnosis of institutions and organizations involved in risk management and disaster mitigation
		Scale variation according to the object of analysis, oscillating from 1:1,000,000 for national scale, up to 1:2,000 for local scale	Risk identification and assessment
			Establishment of strategies and plans of actions to reduce risks
			Continuous improvement in relation to risk management

2. Determination of geographical scales and assessment of risk boundaries (Milanés 2014; Milanés et al. 2017b). Use of geographical information systems to analyze combined dangers and draw maps including areas in danger of temporary coastal sea-flood caused by hurricanes of different categories (I, II, and V). At the same time, permanent flood scenarios of sea-level rise, up to 2050 and 2100, have to be also represented on multidanger maps (see Fig. 2). In this way, all the assessed information, zones of the territory exposed to danger, boundaries of areas for future zoning, and ordering of coastal regions are also geospatially represented on the maps.
3. Presentation of proposals about preventive, prospective, and corrective actions, including specific actions for

financial protection (Guasch et al. 2008; Milanés et al. 2017a). Those actions must include tasks for preparation and responses to the destructive effects of the threat to guarantee protection to population and economic goods. Once the event is over, a recuperative phase must be declared to rehabilitate and reconstruct all vulnerable urban and eco-systemic elements, among other necessary actions. The measures taken for risk and damage mitigation (ICAM 2009) must be assessed for repetition of other kinds of risks in the near or far future. Three strategies for damage mitigation: protection, accommodation, and retreat, have been stated by Bijlsma et al. (1996) (see Fig. 3a–c).

Coastal Risk, Fig. 1 (a) Normal tidal conditions: low water in coastal lowlands (Source: Modified from ICAM (2009)). (b) Tropical cyclone conditions: high water in coastal lowlands (Source: Modified from

ICAM (2009)). (c) Tropical cyclone conditions: high water in coastal lowlands; storm surge conditions or extra-tropical storm; coastal lowland flooding and surge level (Source: Modified from ICAM (2009))

Coastal Risk, Fig. 2 Analysis of scenarios of combined danger in case of sea-level rise caused by climate change and hurricanes of different categories

Conclusion

The peculiar characteristics of coastal zones of being fragile geographical areas exposed to threats of different origin, which can cause numerous disasters if not managed properly, give great importance to studies about coastal risks.

The theoretical frameworks and various terms about coastal risk analyzed in the present chapter, lead to conclude that vulnerability constitutes an inner risk factor of urban coastal zones because of the probability of those areas to be affected by natural or anthropic threats, and the capacity of the corresponding authorities and institutions to face them. As it is generally impossible to modify threats, and eliminate or minimize coastal risks, the alternative for reducing their consequences is, therefore, to increase knowledge about vulnerabilities.

Vulnerabilities of a coastal urban environment are conditioned by the following eight factors: (1) location of human settlement at the first coastal line; (2) number and density of

settlement population; (3) restriction to access or mobility of resources; (4) absence of basic medical services; (5) degradation of habitat and ecosystems of natural or built environment due to the climate change; (6) poor economic, political, institutional, and governmental will, at different levels, to manage risks; (7) poor, or null, urban – territorial planning; (8) absence of integrated approaches in preventive studies about threats, vulnerabilities, and risks.

Numerous advantages were observed when assessing some methodologies for coastal risks, e.g., to help in using the land properly, in taking actions for urban ordering and planning, and in proposing future options for areas free of risks; to be significant indicators for environmental management of urban-coastal zones and for the establishment of governmental politics and plans of response at different levels; to help in determining the environmental impacts to be taken into account for future projects, and in keeping the sustainable development of all the spaces used; to help in doing holistic analysis of threats, vulnerabilities, and risks as a contribution for urban zones to increase resilience to all kinds of threats.

Coastal Risk, Fig. 3 (a) Anthropic structure for protection (pier or jetty). Hard solution. (a1) Protection with natural element (mangrove). Restoration or *soft solution* (Source: Modified from Bijlsma et al. (1996)). (b) Accommodation (Source: Modified from Bijlsma et al.

(1996)). (c) Retreat. (c1) Controlled retreat and territorial planning. Urban proposal for external public areas at vulnerable zones (Source: Modified from Bijlsma et al. (1996))

Recommendations about the best practices for risk mitigation include responses of Hard and Soft Engineering to possible impacts, reducing, therefore, exposure to different kinds of dangers. Additionally, nonstructural and adaptable actions, environmentally sustainable, like: reforestation, rehabilitation, and, if necessary, relocation of vulnerable communities to safer places, are proposed in the present chapter. Measures aimed to build special structures for emergency shelters have to be taken in case of communities having no other choice than living on land in great risk of floods.

Definition

Scenery has been analyzed in a variety of ways, and a lack of consensus exists as to the precise source of its aesthetic quality via the expert and perception-based approaches, culminating in landscape/seascape character assessment approach techniques being assessed. A semi-objective methodology utilizing weighting parameters and fuzzy logic mathematics is given as an example to assess coastal scenery, in which the main parameters (26) that influence people's assessment of coastal scenery were obtained from over >1000 beach interviews.

Introduction

The importance of landscapes to society for recreation, spiritual nourishment, and posterity has long been recognized. Some landscapes are intrinsically more important than others and designated as such by the plethora of existing classifications, e.g., "national parks," "heritage coasts," "areas of outstanding natural beauty," "wilderness areas," "protected landscapes," and "green belts" all reflect scenic beauty. Because of coastal tourism, beautiful coastal scenery is an asset to any community and an economic resource and therefore not a disposable luxury resource.

In recent years the number of people visiting scenic coastal landscapes for recreational purposes has increased dramatically, and correspondingly it is necessary to protect and conserve these attractive landscapes. Environmental managers have been faced with a dilemma: should coastal landscape development be impaired for the sake of conserving the

natural scenery or not? This revolves around which landscapes are favored by society and requires the use of techniques that evaluate the relative quality of scenery so that comparisons can be made according to resource user's needs. This is particularly significant to coastal scenery, as coastlines currently face enormous pressure from anthropogenic factors seeking to develop the area to facilitate activities, such as tourism and residential housing, and studies have shown that excellent scenery is a prime tourist factor in choosing a beach holiday – the others being water quality, safety, no litter, and facilities, the weightings varying with destination selection, resort to remote (Williams and Micallef 2001).

Establishing a coastal scenic evaluation technique that is credible and accurate has often proved difficult. Scenic evaluation can be as basic as observers pointing to features, such as, trees, water that enhance the view, as against pylons, industrial chimney stacks that disfigure it. Observers will not/cannot see the same landscapes, and the effects of elements in the form of numbers, colors, etc. might be in agreement, but the facts only take on meaning through association. There is a lack of consensus regarding the precise source of aesthetic quality: is it inherent in the physical landscape or is it a psychological product? The former theory is termed the objective paradigm and the latter the subjective paradigm, and these opposing premises underpin two approaches to any landscape evaluation: the "expert" and "perception-based" approaches, respectively. The expert approach relies on a standard of assumptions made by an expert surveyor regarding attractive and unattractive scenery, and each landscape is evaluated according to this standard, e.g., Fines (1968) and Linton (1982). Since Leopold's (1969) seminal paper, the academic study of scenic assessment has developed, and it is now possible to apply some form of scenic assessment to any landscape or scene, and this is increasingly relevant to coasts. This approach has been largely rejected by the academic world because it assumes that scenic preferences are homogeneous between individuals. However, scenic appreciation is dependent on a complex interaction of factors with the precise influence of each being invariably interlinked. These factors include psychological constructs and sociodemographic variables, which combine in different ways to trigger a unique emotional response when an individual views a landscape. Perception of coastal scenery is therefore by no means universal and varies from person to person, and for this reason, the methodology of an objective "expert" evaluation can be viewed as erroneous.

Landscape/scenery is bound up in semantics. Sauer (1963, 319) defined landscape as "... an area made up of distinct association of forms, both physical and cultural... The content of landscape is found...in the physical qualities of the area that are significant to man and in the form of his use of the area... In facts of physical background and facts of human culture," i.e., the natural landscape is present in preman's activities and a cultural landscape fashioned from the natural by the activities

Srøksnes, T (2017) 'The landscape is not in front of me. It's all around me', 'Sharkdrunk', Jonathon Cape, 320 pp.

of a cultural group. It is composed not only of what lies before the eyes but what lies within the heads. Different groups of people view landscapes in different ways, e.g., a geologist will look first at rocks and a botanist at flora. Scenery on the other as defined by any dictionary is the aggregate of picturesque features in a landscape. Scenic beauty is deemed to be the central dimension of man's relationship with the environment representing the highest quality common factor derived from focused acts of environmental appreciation, and it is a prime factor in landscape evaluation. It evokes aesthetic responses that form part of a hierarchy of values representing a source of self-actualization for which *Homo sapiens* strives once basic biological/psychological needs are met.

Evaluation simply implies choice/comparison between two or more defined landscape areas, and the evaluation procedure should have clear aims, which should involve certain features: the ability to observe, assessment/measurement criteria, a theoretical basis, a means of recording/summarizing/ interpreting, and communicating the measurements. So, what and why do people like about landscapes, as these words are of concern for coastal management, waterways, land areas, etc.? Frissell et al. (1980, 160) referring to Yosemite Valley National Park, the first in the USA and founded in 1864, wrote "... it is the will of the nation embodied in the Act of Congress, that this scenery shall never be private property, but that like certain defensive points upon our coast, it shall be held solely for public purposes."

Different approaches have been devised mainly of a subjective nature, but more and more public preferences and the use of photographs have taken center stage; however, two main problems exist:

- Defining a landscape that people enjoy and responses to a given landscape and the psychology of environmental perception varies enormously.
- Describing aesthetic values quantitatively – essential for resource users.

History and Problems Associated with Landscape Evaluation Techniques Regarding Scenery

No one doubts the need for landscape evaluation, but no one can agree as to how to go about it. Evaluation, having diverse objectives encompassing preservation, protection, recreation, etc., is concerned with quantifying matters into numbers and distributions which can then be turned into maps, graphs, etc. Initial attempts at scenic classification aimed at direct measurements (Fines 1968; Leopold 1969), but with no underlying theory, the opinion of "users" was initiated. This did not decry the use of "experts" but provided a level playing field for both professionals and the man in the street. Objectivity was frequently claimed, but subjective judgments became the norm. Most techniques failed to take into account

the scenic quality at a point and the views from all directions from that point. Can one consider a piece of land in isolation? Many direct methods depended upon a gross scoring method with broad generalization and no formal recognition of basic aesthetic principles in the determination of scores assigned.

(a) **Measurement techniques.** Three environmental conditions have to be accounted for in any technique: the state of mind of the observer, the context of observation, and the landscape itself (environmental stimulus). Landscapes are dynamic elements constantly changing day to day, year to year, via weather, erosion/deposition processes, etc., so surveys must be done in a short time span and in comparable weather conditions.

(i) *Observer choice.* Differences in personality usually mean that visual beauty is felt differently. Training could increase the receptivity to beauty, but it could also constitute a potentially influential variable. Is there a "good fit" between a small group of "experts" and the public?

(ii) *Observer number.* Traditionally one or two people were involved in order to have consistency, but these were not necessarily a representative sample. Higher numbers are needed to give composite judgments.

(iii) *Scoring scales.* A lone observer could use a personal scoring scale but not if the results were to be compared with another observer at another site with his/her personal scale. Usually the observer gave a score within set limits, e.g., equal interval scales (1, 2, 3, 4, 5, etc.), geometric scales (1, unsightly; 2, 4, 8, 16, 32, spectacular; Fines 1968), or nominal grades (low, medium, high). Problems with ordinal/rank scales are that they are not open ended making an observer reluctant to give the highest/lowest score. Comparisons between areas are difficult due to the large variety of these scoring scales. Linton (1982) divided landscape into landform (1, lowland, to 6, mountains) and landscape (1, urban/industrialized, to 7, wild) and in addition gave a number suitable for planning purposes. Leopold (1969) in a response to Snake River dam building did away with numbers by utilizing five attributes (ugly–excellent) to expand upon 46 physical, biological, and human factors deemed to be important in scenic assessment, looking at valley and river character, and based assessment upon uniqueness.

(iv) *Measurement units.* Landscape designers required the total field of observation to be defined, and a number of techniques adopted the 1 km² as a base unit, e.g., Coventry-Solihull-Warwickshire (CSW 1971), who delineated 24 prime factors, e.g., 1, hedges/trees; 15, listed buildings; and 23, views, and utilized step-wise multiple regression analysis to find out how far variations between measured factors of 1 km² and

those of another accounted for variation between square scores. The problem was defining the grid square on the ground. Other units included the drainage basin, parish, and landscape tracts.

- (b) **Mathematical techniques.** Landscape beauty is frequently dependent upon subtle characteristics of its components, which the eye can appreciate completely. The visual management techniques of the CSW (1971) study were lengthy and complex including a large number of separate evaluations resulting in a decision rule. Showing a great insight for future work in this field, Shafer and Brush (1977, 255), argued that "... not to use mathematics to help explain phenomenon of landscape preferences would be like trying to fell a tree with a chain saw without turning on the power switch." Multiple regression analysis was a common tool (Shafer and Brush 1977), as it took into consideration not only changes in the landscape variables but also the many subtle and unsuspected interactions between the variables. In environmental impact assessment, scenery is also measured by several methods, which evaluate the loss of beauty or homogeneity caused by a certain project or activity, normally through variable, such as extension, intensity, or accumulation summed in a single equation.
- (c) **Public preference techniques.** These had no practical limitations as the main concern was the use of surrogate measures and definitions of the nature of landscape. Problems arose from the fact that many surveys invariably asked questions of people who were already on sites, with the obvious risk of sample bias by persons who were attracted by the landscape to be present in the first place, but surely it is best to ask questions to respondents about scenery that they knew. Inherent familiarity can affect results either positively or negatively. Scenic preferences can be affected by content, e.g., water, tree, interest, and expertise. Controversy exists as to whether socioeconomic factors (upbringing, attitudes) play a part. Photographs have been used as surrogates for actual site visits, mainly because of cost. In this type of media, filtered reality can be biased, e.g., taken from the photographer's viewpoint. Williams and Lavalle (2001) showed that photos taken with a 50 mm lens when compared with an observer's view of the same scene (a box placed around the observer's head gave the same view as the exact scene photographed) and later tested via a t test showed that the null hypothesis was correct. Public attitude questionnaires (Penning-Rowsell 1989) can be subdivided into techniques having a strong factual basis (Leopold 1969), weak or nonexistent factual basis (Fines 1968), and evaluation based on landscape values (Penning-Rowsell 1989).

Amalgamation of subjective, objective, measured, and spoken seems to be the way ahead for future techniques in order to produce a technique suitable for areal comparison. Scenic

evaluation emerged mainly in the mid-twentieth century, as a technique for landscape classification and description, identifying particular landscape types or landscape features by referring to specified value criteria. The late twentieth century represented a watershed in the jettisoning of the idea of man's domination over nature to one of more respect, which unfortunately in the twenty-first century does not hold sway in many parts of the world, e.g., the Amazonian or Poland's Bialowieza logging industry a UNESCO Natural World Heritage Site. Logging is banned on the Polish side of the Belarus border, which accounts for only 17% of the whole forest.

An innovative technique based upon Leopold's (1969) seminal paper produced a coastal scenic evaluation system based upon parameter selection obtained from several thousand interviews (Europe, USA, New Zealand), as to what parameters are needed for "good/bad" coastal scenery (Ergin et al. 2004). Twenty-six were deemed prime factors, and making use of Leopold's (1969) five-item attribute idea, these were weighted and subjected to fuzzy logic analysis to produce histograms, weighted averages, and membership degrees culminating in a "D value." This has been applied to >860 beaches worldwide. The D value classified locations into five scenic classes (I, excellent, D value >0.85 to V, poor, D value <0; Fig. 1).

In the twenty-first century, landscape/scenic assessment mutated into Landscape Character Assessment (LCA) defined as "a distinct, recognisable and consistent pattern of elements in the landscape that makes one landscape different from another, rather than better or worse" (LI 2016, 2). It was a quantum leap in scenic/landscape assessment, aided by the rise of computer power and satellite imagery and one which is still evolving (Fig. 2; Tudor 2014).

Landscape Character Assessment factors, i.e., natural (e.g., geology), cultural (e.g., land use), aesthetic (visual), and associations (e.g., history), have been incorporated into a LANDMAP (Landscape Assessment and Decision Making Process) system, via a partnership program between the Countryside Council for Wales (now Natural Resources Wales) and all the unitary and national park authorities of Wales (CCW 2001). Datasets recorded information about the characteristics, qualities that influence the geology, habitats, visual and sensory, historical and cultural on the landscape managed through a Geographical Information System, i.e., 5 map layers in a GIS format. It was a benchmark publication and a tool for assessing landscape resources to aid decision-making and natural resource planning at a range of levels (local to national) where landscape characteristics, qualities, and influences on the landscape are recorded, and areas were shown as single polygons (or polyline) in a single map layer. Scales utilized were typically 1:250,000, 1:50,000 or 1:25,000, 1:10,000, or larger scales. LCA has now been added to seascape character assessments, i.e., landscapes with coastal/sea views, so that coasts together with the adjacent marine environment which have natural, cultural, historical, and archaeological links with each other are dealt with as a whole, i.e., "an area of

Coastal Scenery, Fig. 1 (a) Ursa, Portugal, Class I; (b) Newton, Porthcawl, UK, Class III; (c) Galerazamba, Colombia, Class V (red colors, physical parameters; blue colors, human parameters)

Coastal Scenery, Fig. 2 Landscape Character Assessment and judgment making (NE 2014)

sea, coastline and land, as perceived by people, whose character results from the actions and interactions of land with sea, by natural and/or human factors” (NE 2012, 8). It covers five key principles:

1. Landscape is everywhere and all landscape and seascape have character (Srøksnes 2017).
2. Seascape occurs at all scales and the process of seascape character assessment can be undertaken at any scale.
3. Seascape character assessment should involve an understanding of how the seascape is perceived and experienced by people.
4. Seascape character assessment provides an evidence base to inform a range of decisions and applications.
5. Seascape character assessment.

Summary

Various techniques (measurement, mathematical, and public preference) have been utilized to assess coastal scenery and an innovative one introduced using weighting and fuzzy logic mathematics, which can be used rapidly in both landscape/

seascape character assessments. Perhaps for the future remotely sensed satellite, data could be a key factor, as data can be digitally processed for landscape classification into major physical divisions. These approaches would allow large landscape descriptions to be made rapidly. It also provides a framework for landscape surveys and evaluations to be made where basic map data is lacking or field survey resources limited.

Synonyms

Bathymetry; Coastal cartography; Coastal classification; Coastal geomorphological maps; Nearshore classification; Seafloor mapping; Seafloor topography

Definition

Coastal seafloor classification is based on the recognition of submarine features depicted by bathymetric patterns that are interpreted in terms of topography of marine origin or the identification of drowned terrestrial landforms. Coastal

seafloor geomorphological maps are usually the products of interpretation, visually displaying digital bathymetric patterns through either cognitive reasoning or the result of computerized autoclassification algorithms. There are advantages and disadvantages associated with each approach (computerized autoclassifications versus cognitive interpretations), and the choice of procedure depends on purpose. Both methods are beneficial classificatory approaches, as they complement each other when interpreting coastal seafloor geomorphological features.

Introduction

Although there are many different methods for classifying seafloor features, most have a special purpose with specific goals that rely on the product of the survey technique (e.g., Finkl and DaPrato 1993; Mumby et al. 1998; Greene et al. 1999; Finkl 2004a, b; Mayer 2006; Collins et al. 2007; Chust et al. 2008; Walker et al. 2008; Achatz et al. 2009; Brock and Purkis 2009; Finkl and Vollmer 2011; Pittman et al. 2013; Makowski 2014; Finkl and Makowski 2015; Makowski et al. 2015, 2016, 2017; Makowski and Finkl 2016). The exemplar of the southeast Florida continental shelf has been studied using remote sensing techniques since the 1960s. The basic framework of these specific shelf features were outlined for the first time in reconnaissance seismic reflection profile surveys conducted by Duane and Meisburger (1969). Spatial distributions of shore-parallel coral reef tracts, inter-reefal sediment-filled troughs, and outcrops of carbonate bedrock were identified in their seismic reflection profiles. Subsequent LIDAR (light detection and ranging) surveys (2001 and 2008) in the form of LADS (Laser Airborne Depth Sounding) produced remarkably detailed depictions of shelf bathymetry. This kind of digital data is amenable to color ramping where tonal variations can be keyed to depth. Combinations of texture, tone, and pattern in the digital data provide a basis for cognitive (manual) interpretation of seafloor features. Maps showing spatial distribution patterns of seafloor features, for example, those prepared by Finkl et al. (2005a, b, 2007), Finkl and Andrews (2008, 2009), Finkl and Vollmer (2011), Steimle and Finkl (2011), Finkl and Makowski (2015), Makowski et al. (2015), Vollmer et al. (2015), Makowski et al. (2016), Finkl and Vollmer (2017), and Makowski et al. (2017) all recognize a range of marine landforms and drowned subaerial forms.

Cognitively derived (i.e., manually interpreted) maps are normally composed by hand and based on visual inspection, after which the mapping units are transferred into some sort of georeferencing informational software (e.g., ArcGIS). Finkl and Makowski (2015) have shown that it is possible to classify bathymetric patterns using automated computer algorithms, such as unsupervised isoclustering and interactive

supervised autoclassifications, which were then compared with previously prepared cognitive maps of field-verified seafloor features.

A good example of this involves the digital format of LADS (LiDAR) data, which makes the autoclassification of seafloor bathymetry possible. The basic procedure is to select a subset of the overall digital bathymetric dataset and compare the previously cognitive-identified geomorphological features (as described by Finkl et al. 2004, 2005a, b, 2008; Finkl and Andrews 2008, 2009; Finkl and Banks 2010) to auto-generated classifications of the same area. In order to determine whether autoclassification algorithms produce results comparable to cognitively interpreting, it is advisable to conduct a series of autoclassifying tests in appropriate geographical information system (GIS) software (e.g., ESRI's ArcGIS ArcMap).

In the example of the study area on the continental shelf off southeast Florida, the computerized classification of LADS digital bathymetry was divided into two parts, unsupervised isocluster and interactive supervised methodologies. Iterations of both methods were used to discern comparability with known seafloor geomorphological distribution patterns. Pixel digital numbers (DNs) were based on variations in color derived from color ramps that were applied to the DEM. Critical to this procedure is the number of classes that are discriminated by computer runs. Experimentation shows that

a large number of autoclasses produces patterns that generally are not comparable with previously cognitive-derived geomorphological maps (Finkl and Makowski 2014; Finkl and Makowski 2015). Iterations using a dozen or so classes produce recognizable patterns in interactive supervised classifications, whereas unsupervised isocluster autoclassifications require ten or fewer classes. Details of the autoclassification procedures are briefly summarized as follows.

Unsupervised Isocluster Autoclassification Method

Within ArcMap, the Image Classification toolbar needs to be activated and an unsupervised isocluster autoclassification performed on a subset of the study area. After the appropriate input raster (composite of the RGB bands) is selected and the output-classified raster is renamed in the proper geodatabase, the number of classes is assigned using the same number of features interpreted from cognitive processes. In the LADS subset, for example, where 14 geomorphological features were cognitively interpreted, the number of untrained classes assigned for the unsupervised isocluster autoclassification was 14. Because untrained class counts greater than 10 for unsupervised isocluster analysis of the LADS bathymetry tends to produce unusable results (cf. Fig. 1), additional

Coastal Seafloor Geomorphological Features, Classification, Fig. 1 Uninterpreted spatial distribution patterns derived from unsupervised isocluster analysis of LADS bathymetry DEM using five classes (left panel), seven classes (middle panel), and 14 classes (right panel). The larger number of classes in the third panel shows that

increasing the number of classes does not necessarily improve discrimination of the imagery because, even though the same gross patterns are evident, the increased number of classes requires additional field verification. (Source: Finkl and Makowski 2015)

unsupervised isocluster classification analyses were performed with five and seven untrained classes, after which individual output rasters were saved as Tiff image files and imported as layers into ArcMap adjacent to the raw images. These displays can then be exported and visually compared with cognitively interpreted displays of the same imagery to visually determine the degree of correlation of autoclassification.

Interactive Supervised Autoclassification Method

Within ArcMap, the Image Classification toolbar is activated, and an interactive supervised autoclassification performed on the same subset as the unsupervised isocluster method. Once an individual scene is selected in the drop-down window from

the Classification toolbar, the Training Sample Manager window is opened. Training sites can then be established for the interactive supervised classification that corresponds to pixel patterns used previously for cognitive interpretation of the seafloor features. For example, in the LADS digital dataset where 14 geomorphological features were cognitively interpreted, 14 training sites were established for the interactive supervised classification to match the visual cognitive criteria. The training fields shown in Fig. 2 contain variable shapes that are determined by geomorphological landform patterns. Selection of training fields is critical because they have to represent the feature or pattern that is autoclassified. The operator must therefore accurately train the program to recognize specified features or patterns.

After the interactive supervised classifications are performed, individual output rasters can be saved as Tiff

Coastal Seafloor Geomorphological Features, Classification, Fig. 2 Locations of training fields used for the interactive supervised autoclassification of uninterpreted LADS digital bathymetry. Training sites represent the main landform features on the continental shelf, as determined from cognitive interpretation of texture, tone, and pattern

observed in the color ramped DEM, which was then interpreted in terms of field-verified geomorphological features. The training sample manager legend shows matched pairings of landform class names with a training field color. (Source: Finkl and Makowski 2015)

Coastal Seafloor Geomorphological Features, Classification, Fig. 3

Cartographic examples of methodologies based on unsupervised isocluster analysis with five classes (left panel) and interactive supervised autoclassification with 14 classes (right panel). Both examples show organization of bathymetric patterns that variably correspond to cognitively interpreted landform units on the seafloor. Generalization and increased discretization is evident in both examples, as the number of classes required is dependent upon the purpose of the classification and the amount of detail needed. (Source: Finkl and Makowski 2015)

image files and imported as layers into ArcMap adjacent to the raw LADS images. These displays are then exported and visually compared with the cognitively interpreted maps to visually estimate the degree of correspondence with the autoclassification. Results of autoclassifying bathymetric data are shown in Fig. 3 where the left panel contains unsupervised isocluster classification using seven untrained classes and the right panel shows spatial distribution patterns derived from an interactive supervised classification using 14 trained classes.

Comparing Classification Results

Visual comparison of the autoclassification results with a control shows a gross correspondence between the unsupervised isocluster autoclassification and the control. Detailed comparisons can, however, get complicated along the shore where three units are differentiated for the single larger bar and trough units on the LADS imagery (Fig. 4a). Bathymetric texture, tone, and pattern attributes are detected in the unsupervised isocluster classification, suggesting a basis for discerning discrete landform units. Ground truthing is required to verify units in the unsupervised isocluster autoclassification, but in situ familiarity with ground conditions suggest the following features: a surf zone unit close to the shore, crenulated bars alongshore, and fans or sediment spays seaward (Fig. 4b).

On the other hand, the interactive supervised autoclassification shows more complex spatial distribution

patterns that correspond to parts of the cognitive map, as shown in Fig. 5. This map may seem confusing because it is a montage of two different approaches for depicting seafloor geomorphology. Careful study, compared to a cursory glance, shows many important interrelationships. Starting at the shore and moving seaward, for example, the interactive supervised autoclassification matches the cognitive interpretation. Additional detail is provided in the form of distributions for nearshore sandflat, offshore sandflat, and hard-bottom outcrop.

Classification Determination and Validity

Before modern computerized mapping and GIS software packages, maps were validated in the field and compared with other maps known to be accurate. Although validation and accuracy assessments of computer-aided maps are usually achieved by statistical procedures and mathematical evaluation of self-tests, the visual comparison of machine-classified maps versus cognitively derived maps is simply a measure of correspondence. The advantage of these modern procedures lies in the pros and cons of an unsupervised isocluster autoclassification methodology and an interactive supervised autoclassification methodology when compared with mapping units based on the ratiocinative powers of the human brain. This process shows the possibility of producing composite maps of digital bathymetry.

Coastal Seafloor Geomorphological Features, Classification, Fig. 4

Comparison of unsupervised isocluster analysis (right panels) with unclassified (a) and classified (b) ramped LADS DEM. (a) Five-class unsupervised isocluster analysis (right panel) compared with (uninterpreted) color ramped bathymetry (left panel) showing the general correspondence of shore zone bar and trough features, coral reef tracts, bedrock outcrops, and dredge pits for beach nourishment projects. Symbolization of the geomorphological seafloor features is given in the legend to Fig. 6. (b) The same five-class unsupervised isocluster analysis (right panel) compared with cognitively interpreted geomorphic features on the shelf (left panel). These figures show generalization that occurs in maps hand-drawn at a nominal scale of 1:600 compared with greater detail that is acquired in autoclassification. (Source: Finkl and Makowski 2015)

Rationale for Classificatory Design

Digital bathymetric data provide new opportunities to investigate the nature of seafloor topologies. Digital data provide a dense sampling medium that can be manipulated to form a DEM of seafloor bathymetry. Elevations can be

exaggerated to emphasize topographic differences that assist cognitive interpretation processes. A color ramp keyed to bathymetry can be draped over DEMs with an assumed light source to produce shadows. This colored representation of seafloor topography lends itself to visual inspection and consequent interpretation of

Coastal Seafloor Geomorphological Features, Classification, Fig. 5

Interactive supervised autoclassification (right panel) compared with cognitively interpreted geomorphic features on the continental shelf (left panel; a field-verified, color ramped DEM). This comparison shows the benefits of an interactive supervised autoclassification, which enhances the results of cognitive mapping seafloor features on the continental shelf. Cartographic generalizations in the cognitive maps are refined in supervised autoclassifications where the number of classes can be varied depending on special purpose investigations. (Source: Finkl and Makowski 2015)

bathymorphological features. This kind of observation and interpretation was not possible prior to the advent of digital surveys. The sample density of the LADS surveys (4-m resolution) was sufficiently detailed enough to allow construction of maps that allow interpretation of mesoscale geomorphological features (e.g., Finkl et al. 2004, 2005a, b, 2008; Finkl and Andrews 2008, 2009; Finkl and Banks 2010). This procedure is a major advance in the study of clear-water continental shelves and permits researchers comprehensive views of seafloor topologies.

Not all digital bathymetric data are amenable to automated classifications of the type applied to digital aerial and satellite images. In the case of hyperspectral data, for example, unsupervised classifications are more or less inept for interpretation of seafloor features. There are many reasons why hyperspectral data, usually measured with hundreds of narrow spectral bands about 10 nm apart, have prohibitive use for classificatory purposes. For example, in order to accurately obtain spectral signatures from hyperspectral data for different entities, such as different phytoplankton classes, zooxanthellae clades, or scleractinian (i.e., hard coral) species, it is necessary to first provide in situ spectral information. Without this information, the imagery cannot be interpreted because a function of the natural spectral variability is unknown. One such effort took place at Buck Island, St. Croix, U. S. Virgin Islands, where hyperspectral data obtained by AVIRIS (air-borne visible infrared imaging spectrometer)

was used in response to a mass coral bleaching event in the Caribbean. Kruse (2003) used the visible spectrum of AVIRIS light data reflecting off the coral reef and the surrounding reef bottom in order to estimate the extent of the bleaching, as well as the overall health of the coral colonies. Underwater handheld spectroradiometers first had to be used to measure reflected light readings from bleached coral so the hyperspectral imagery data could be calibrated to the in situ reflectance readings for an accurate interpretation. The procedure also requires that special geometric and atmospheric correction techniques are used to recalculate hyperspectral image pixels with data values that correspond to reflectance from the precise locations of those pixels. The main disadvantage is that the nominal spatial resolution of hyperspectral data is necessarily lower in order to maintain an acceptable signal-to-noise ratio. This condition is a function of fewer available photons in the narrow hyperspectral bands to interact with a sensor's detector elements. The consequence of this condition is very little image resolution to aid in the visual interpretation of the coastal environment. Lee and Carder (2005) recognized that a more cost-effective multispectral sensor is preferred over hyperspectral imagery when evaluating the major properties of coastal or shallow-water environments. Because digital bathymetry does not retain these disadvantages, there is an opportunity to investigate the possibilities of auto-classification procedures.

Unsupervised Isocluster Autoclassification Benefits and Limitations

The efficiency of unsupervised pixel clustering depends on the visual properties of the image being classified. Color ramped bathymetric DEMs generally do not offer a specific enough delineation of spectral signatures across the image. That is, if too many pixels with similar spectral properties are detected in multivariate space within the color ramped DEM, then the autoclassification cannot selectively assign different color values to represent specific seafloor landforms. Because the color ramped DEM does not offer enough spectral contrast and there is no cognitive intervention when running an unsupervised isocluster autoclassification, when an increased number of classes is used, each class will inadvertently include a cluster of pixels that carry the same value. When the computer runs the unsupervised isocluster autoclassification and detects the same pixel-valued clusters throughout the color ramped DEM, the same representative color is applied universally.

A potential solution to this problem is to use a greater range of hues in the color ramp applied to the DEM. Although the range of hues selected for a color ramp is arbitrary, the range of hues should be selected for overall visual appearance and arranged by depth. By using a greater range of hues in a color ramp that are keyed to bathymetric variations, it is possible to increase the number of classes in an unsupervised isocluster autoclassification.

Interactive Supervised Autoclassification Benefits and Limitations

Increased efficiency can be expected when applying the interactive supervised autoclassification method across the color ramped DEM. This is because a cognitive element is introduced to supplement the autoclassification algorithm. That cognitive element is presented in the form of analyst delineated training sites, which enclose specific spectral signatures to teach the autoclassification software how to interpret the remaining pixels in the image. This greatly differs from the unsupervised isocluster autoclassification because the analysis is no longer solely reliant on the undefined distribution of pixel values within the color ramped DEM. Instead, individual geomorphological units are taught to the machine by associating very specific pixels hues in the form of training sites. However, the same limitation of the visual properties in the color ramped DEM that was seen with the unsupervised isocluster autoclassification still persists when applying the interactive supervised autoclassification methodology. For example, because the range of hues in the DEM color ramp shows minimal contrast throughout the image, certain geomorphological units are not easily delineated

from one another, even with the provided training sites to guide the autoclassification process. Regardless of this limitation, the interactive supervised autoclassification provides efficiency in the number of seafloor unit boundaries that could never be achieved with cognitive, hand-drawn cartography.

Cognitive Versus Autoclassification Methods

Cognitive mapping is an historical method of approximating spatial distribution patterns on the ground. These efforts were severely limited in the marine environment, and it was not until the advent of remote sensing techniques during World War II that it was possible to conduct regional submarine mapping. Seismic methods, single beam sonar, sidescan sonar, and multibeam sonar techniques provided great advances in the recognition of submarine seascapes, but it was not until the arrival of LIDAR in the 1960s that it was possible to acquire digital bathymetric data at sufficient resolution to recognize discrete submarine landforms on continental shelves. With the ability to create colorized DEMs from digital bathymetric data, it becomes possible to visualize seafloor features as never before seen. The cognitive maps derived from digital bathymetry provide an interpreted picture of seafloor geomorphology, necessarily generalized to a level that is dictated by the hand-drawing agility of the cartographer. Because these kinds of maps are hand-drawn and based on visual interpretation, it does not make them any more or less useful than other kinds of maps. The quality of the cognitive maps depends on the skill of the interpretation from the cartographer. That is to say, the more experienced and qualified the mapper, the more accurate the results. Because researchers without proper qualification and experience find it impossible to produce useful products, a common “solution” is to turn to automated classifications. Unfortunately, a new problem arises because an automated classification produces a map that differentiates the seafloor into different units or classes based solely on pixel arrangement. The key is to know what those units actually represent and where in the seascape they are correctly represented. Those units, however, can only be properly interpreted by those with appropriate training and experience in geomorphology. This oversight, a major pitfall that is associated with many automated classifications, limits the usefulness of auto-classed maps of seafloor geomorphological features.

On the other hand, supervised machine classifications can be very useful and informative, as described by Erdey-Heydorn (2008) and Rozenstein and Karnieli (2011). As in the analogy of a painting, much critical time and effort is required to prepare the canvas compared with the time spent actually painting. The same is true for the interactive supervised autoclassification, as careful consideration must be given to the selection of training sites. Although training

Coastal Seafloor Geomorphological Features, Classification, Fig. 6 This montage was created by digitally overlying an interactive supervised autoclassification on top of a cognitive (manually interpreted) map of shelf geomorphology based on digital bathymetry in a LADS format. Increased resolution is provided in the overlaid autoclassification which gives better discrimination (more details) of offshore sandflats on

top of hard-bottom (pink areas), diabathic channel fields (gray colored areas), coral reef subcrop (orange colored areas), and coral reefs and reef gaps (light green colored areas). Somewhat problematic are some light green areas for reef gaps that may be confused with several other morphological units, such as coral reefs, coral reef subcrop, and overwash deposits. (Source: Finkl and Makowski 2015)

sites can be selected to represent different kinds of variability in the survey area, they are perhaps more valuable if selected to better define known geomorphological features. Such a procedure requires a priori knowledge of the seafloor, which can be obtained from cognitive observation and mapping.

Both techniques in question, cognitive mapping and auto-classification, can be shown with great advantage when used in concert with one another. Each complements the other to help produce a more accurate, comprehensive product. That is, a cognitive mapping product refined by a software-driven autoclassification algorithm, further details the intricacies of

seafloor spatial distribution patterns in the form of digital bathymetry. The cognitive map provides a comparative control, or reference, for the interactive supervised auto-classification. Both products are useful in their own regard but acquire greater usefulness when blended into a composite or montage (Fig. 6).

Both processes, autoclassification and cognitive mapping, have their own sets of constraints that limit approximations of reality in the form of the kinds of maps that are produced in GIS (see for example Benedet and Finkl 2003; Greene et al. 2005; Finkl and Makowski 2015). Each approach has value or

merit, and greater insight into seafloor features can be achieved by applying the composite approach that melds the two disparate methodologies.

Conclusion

Classification of coastal seafloor geomorphological features can be achieved either through a cognitively derived interpretation or an autoclassificatory algorithm run by geospatial software. The interactive supervised autoclassification with expert-derived training sites provides the most discriminative map when compared with cognitive interpretations. Because of this general correspondence, it is possible to overlay the results of interactive supervised autoclassifications on top of cognitively derived units, thereby merging the two interpretations into a composite that highlights the advantages of both methodologies. Modern georeferenced software packages, such as ArcGIS, contain the appropriate type of tool kit extensions for applying a montage process in the production of a computer refined cognitively derived map. By applying both processes in tandem, a more efficient classification effort is achieved.

Coastal Sedimentary Facies

H. Edward Clifton

US Geological Survey, Menlo Park, CA, USA

Introduction

Coastal sedimentary environments include a variety of physical and biological processes, which act on coastal sediment to produce associations of composition, texture, primary sedimentary structures, and fossils. These associations constitute sedimentary facies, lithologically distinct, genetically related components of a sedimentary system, or environmental facies, whereby a set of specific environmental processes imparts a distinctive character to a sediment. Coastal sedimentary facies provide the signature of specific types of coastal deposits and facilitate their identification in the geologic record.

This entry describes some of the more common clastic sedimentary facies associated with open coasts and coastal embayments. For a review of carbonate coastal facies, the reader is referred to Demicco and Hardie (1995). The discussion here also does not address facies of high-latitude coasts or low-latitude coasts dominated by mangrove swamps (see Hill et al. 1995; and Cobb and Cecil 1993, respectively). Many of the facies described here form in both marine and lacustrine settings, although tidally influenced facies are restricted to the marine environment.

For more detailed information on coastal sedimentary facies, the reader is referred to the excellent summaries provided by Reineck and Singh (1973), Davis Jr. (1985), Walker and James (1992), Galloway and Hobday (1996), and Reading (1996).

Coastal Sedimentary Processes

A complex array of processes influence coastal sedimentary facies (Fig. 1). Of these the most important are waves, tides, and biogenic processes. Sediment input is also critical to the facies character (grain size) and to the nature of the preserved deposit (sedimentation rate).

Waves may exist as “seas,” driven by local winds, or as “swell,” generated by distant storms. Swell tends to have longer period and to influence the seabed to greater depths

Coastal Sedimentary Facies,

Fig. 1 Interacting environmental factors and resulting processes that control the development of coastal facies (Modified from Clifton and Hunter 1982)

than do local sea waves. “High-energy” coasts are likely to be dominated by swell. “Low-energy” coasts receive smaller everyday waves, but can experience very large waves during storms.

Waves move sediment by two mechanisms. The passage of waves induces a back and forth orbital motion at the bottom. In water that is deep relative to the size of the wave, this motion is symmetrical in velocity and duration of flow. In shallower water, the motion becomes asymmetric, with short relatively strong landward flow under the crest of a wave and a more prolonged, weaker, seaward flow under the trough (for the conditions under which this asymmetric flow occurs, see the “Stokes wave” field in Komar 1976, Figs. 3–17). The orbital velocity asymmetry is important for promoting the onshore transport of coarser material and bed load in general.

Waves also, as they encounter the shore, generate sustained flow in the form of shore-parallel longshore currents and seaward-directed rip currents. These currents, which form nearshore circulation cells, not only transport sediment, but also shape the nearshore morphology into bars and troughs.

Tides influence sedimentary facies in two ways. The rhythmic rise and fall of the sea changes water depth and locally exposes extensive intertidal flats. It also generates tidal currents that flow alternately landward (flood tides) and seaward (ebb tides). In morphologically complex bays, either the flood or ebb tide is likely to predominate at any one location.

The response of sediment to these fluid motions depends in large part on its textural nature, which is determined partly by local dynamic processes and partly by what is available to the system. Grain size is also a major influence on the rate and

style of bioturbation, which combined with the frequency and intensity of physical processes determine the degree of preservation of physical structures. Bays typically contain abundant silt and clay, which are borne in suspension or move in small aggregates (particularly as fecal pellets) along the bottom. Between the tidal ebb and flood, at high and low water, the flow diminishes, allowing the settling of suspended sediment. This sediment may immediately accumulate on the bottom or it may be concentrated into a dense, highly concentrated fluid that hugs the bottom before deposition.

Biogenic processes are important in the development of coastal facies. Biogenic effects include bioturbation, the generation of distinctive traces, contribution of shell detritus, the fixing of suspended fine sediment by filter feeding and vegetative baffling, and the binding and bioerosion of the substrate. These processes depend on many factors, but faunal activities are particularly sensitive to variations in salinity. Faunal traces in brackish environments tend to be simpler, less diverse, and more likely to be dominated by a single ichnogenus (Pemberton and Wightman 1992) than those made in oceanic salinities.

Sedimentary Facies of Wave-Dominated Open Coasts

Waves are most important on open coasts, where the tides mostly only raise and lower the water level. A fundamental aspect of most open clastic coasts is the *shoreface* (Fig. 2), a relatively steeply inclined (1:200) ramp that extends offshore

Coastal Sedimentary Facies,**Fig. 2** Typical morphologic zonation of a wave-dominated open coast. Considerable vertical exaggeration

from the intertidal *foreshore* zone and merges with a nearly flat (1:2000) inner shelf or basin floor. Its origin is discussed by Niederoda and Swift (1981). The shoreface-shelf transition lies at depths that range from 2 m to 30 m. On prograding coasts, where the sedimentation rate is commonly sufficient to allow for a wave-induced equilibrium profile, the base of the shoreface rarely exceeds a water depth of 10 or so meters.

The *upper shoreface* is equivalent to the nearshore zone, where wave-generated currents predominate. Upper shoreface facies are generally the coarsest part of the coastal system and are characterized by high-angle trough cross-bedding, that is directed parallel to the shoreline (in response to longshore currents) or offshore (in response to rip currents). Modern medium- to coarse-grained nearshore zones are dominated during fair-weather by medium-scale lunate megaripples (dunes) that face and migrate in an onshore direction. Cross-bedding produced by these structures seems rarely preserved, however, in ancient upper shoreface deposits, which seem dominated by storm effects. If gravel is present, it typically is well sorted into discrete beds and layers, and gravel and shells commonly form erosional lags within the deposit. Small, shore-normal gravel-filled gutter casts exist at the base of some gravel beds. Burrowing is common and is dominated by the *Skolithos* ichnofacies, characterized by mostly vertical cylindrical and U-shaped burrows, the dwelling structures of suspension feeders or passive carnivores (Pemberton et al. 1992). The trace *Macaronichnus* is common in fine sand of high-energy coastal deposits and feeding pits of rays or other vertebrates may occur. The thickness of upper shoreface deposits generally ranges from 1 to 8 m, depending on the intensity of wave energy.

A *lower shoreface* facies is identifiable in most pebbly shoreface deposits. This facies, 1–3 m thick, consists of

small pebbles of relatively uniform size in a matrix of well sorted fine to very fine-grained sand. The pebbles occur as scattered clasts, in small clusters, or as thin discontinuous stringers 1–2 pebbles thick. The associated sand may be laminated or structureless, and is indistinguishable from inner shelf sand. The facies results from a combination of offshore transport from the upper shoreface during storms and onshore transport of most of this material by the shoaling waves in the aftermath of a storm. Winnowed by the waves, the coarser material moves landward more slowly and some is trapped in burrows, swales, or other depressions on the seafloor. In the absence of pebbles, the upper shoreface facies may be the only recognizable shoreface component.

On transgressive coasts, *shoreface-attached ridges* extend obliquely into the sea. These ridges, composed of fine to coarse sand, are tens of kilometers long, several kilometers wide, and 5–15 m high. Cores through shoreface-attached ridges show that they consist of an upward-coarsening accumulation of storm-event beds (Rine et al. 1991). Some shoreface-attached ridges show evidence of both storm and tidal influences in their internal structures.

The *beach foreshore* facies lie within an intertidal zone subject to the swash and backwash of the waves. Foreshore sands are typically very well sorted and characterized by planar lamination. Foreshore deposits are generally 1–2 m thick, and if the grain size permits, show an upward-fining. Individual lamina may show inverse grading. Placers of heavy minerals define the upper part of some foreshore deposits. Small vertical burrows and the trace *Macaronichnus* typify the ichnologic signature of the foreshore.

Nonmarine coastal facies of the open coast include eolian dunes, characterized by large-scale landward dipping foresets and backshore facies of wind/tidal flats. The character of the *backshore* facies depends on the specific setting and the

amount of vegetative growth. Backshore sand is commonly fine and well sorted; layers of pebbles and coarser sand are introduced during floods, and layers of muddy and/or peaty sediment can develop under wetter conditions. Structures such as climbing adhesion ripples or vertebrate footprints document subaerial exposure. Roots are common, and substantial coals may directly overlie the foreshore facies in some ancient deposits.

Mudflats dominate some open coasts proximal to, or down-current from, the mouths of large mud-bearing streams (see Augustinius 1989). In settings such as the coast of Surinam, inshore fluid mud maintains its presence by frictionally reducing the energy of incoming waves. Episodically, mud deposition ceases, either during storms or because the mud moves along the coast in discrete waves, and sandy beaches develop. A return to muddy deposition isolates the sandy sediment in shore-parallel ridges or *cheniers*. Cheniers on the coast of Surinam are about 2 m high and contain a combination of steeply and gently landward dipping cross-beds or, where fine-grained, gently landward and seaward-dipping cross-beds. Cheniers adjacent to the Mississippi River contain shell aggregates concentrated by storm waves. Mud in the associated flats may be laminated to structureless; mudflats covered by salt marshes will contain root or rhizome structures.

Sedimentary Facies of Deltaic Coasts

Deltas form where sediment discharged at the mouth of rivers exceeds the capacity of marine processes to redistribute it fully. As sites of substantial sediment accumulation, deltas form a volumetrically important part of the sedimentary record. Deltas fall into three end-member types depending on whether they are dominated by rivers, waves, or tides. River-dominated deltas are lobate and commonly quite muddy; the modern Mississippi River delta is a prime example. Wave-dominated deltas have a classic deltoid shape and are more likely to be sandy; the Niger River delta is a commonly cited example. Tide-dominated deltas are less common, and tend to be muddy or sandy and highly embayed. The Fly River delta of Papua New Guinea is a primary example.

Distributary channels, which develop on delta plains where a primary fluvial channel diverges into a series of straight or sinuous distributaries, are common to all types of delta. A balance of fluvial discharge and tidal range determines the extent of salt water intrusion into the lower reaches of the distributary and the degree of tidal influence. Distributary channel floors are erosional and typically littered with lags of mudclasts and/or plant detritus. Three-dimensional subaqueous sand dunes in the thalweg produce trough cross-bedding. Higher on the channel banks the sediment becomes finer and is likely to be dominated by ripple bedding.

Reversals of cross-bedding direction will occur where tidal range is sufficiently great. The nature of burrowing depends on salinity ranges in the distributary. If salinity is low or highly variable, the burrow types are likely to be greatly restricted.

The deposits of the distributary channels typically display an upward coarsening, and may pass upward into muddy levee deposits where complete. Clinoforms may mark the upper part of a distributary channel fill. Cross-sections of the deposits formed by relatively straight distributary channels show a deep central channel flanked by broader lateral extensions ("wings") near the top.

The banks of the distributary channels are capped by *levees*, ridges composed of fine-grained sediment at either side of a channel. Levee deposition occurs during submergence associated with major floods. Internal structures of levees include ripple lamination and small-scale cross-bedding, roots, and in some cases bioturbation.

Deltaic bays are associated with lobate (typically river-dominated) deltas and represent settings of low energy in which the prevailing sedimentation is from suspension, including much organic matter. Episodic influxes of silt and fine sand during floods produce coarser laminae, which may be well preserved in brackish settings where faunal reworking is diminished. The shallower parts of deltaic bays commonly are somewhat sandier and may display evidence of wave reworking in the form of hummocky cross-stratification. Plant growth along the edge of a bay may inhibit the development of normal beaches.

Crevasse splays and deltas accumulate where floodwaters breach a levee and carry fine sand and silt into an adjacent deltaic lake or bay. The resulting lobate deposits become progressively thinner and finer with distance into the bay. Internal sedimentary structures include ripple- and planar-lamination, climbing ripples, trough cross-bedding, and mud drapes. Graded beds, and, near the breach, erosional surfaces, define the deposits of separate floods. Dewatering or other deformational structures are fairly common in these rapidly deposited sands. The upper part of individual flood deposits may be bioturbated, where salinities permit. Splays may amalgamate into coarsening-up crevasse deltas, which resemble other small deltas.

Distributary mouth bars develop where distributary channels of a river-dominated delta debouch into a basin (Fig. 3). They consist of coarsening-up accumulations of fine-grained or silty sand. Deposition occurs mostly during flood stage, but the resulting deposit can be partly reworked by waves or tidal currents. Internal structures include ripple, climbing ripple, and planar-lamination. Flaser bedding may be present, as well concentrations of wood or finely divided organic detritus.

Beyond the actual mouth of a distributary lies the *delta front*, an area dominated by flood deposition and possible reworking by waves. Delta front deposits of river-dominated

Coastal Sedimentary Facies,**Fig. 3** Morphologic elements and facies at the mouth of a river-dominated delta lobe

deltas typically consist of interbedded fine to very fine grained sand and mud. Ripple lamination is a common internal structure of the sands, although storm waves can also generate hummocky cross-bedding in this environment. Some graded sand beds appear to be deposited by sediment gravity flows, and deformational structures are common. Bioturbation may be intense to limited depending on the volume of freshwater discharged into this setting. Delta front deposits grade down into *prodelta* muds that form the deeper-water foundation of a delta. Facies on the fronts of wave-dominated deltas may be indistinguishable from those of an open-coast wave-dominated shore.

Tide-dominated deltas have received less study than river-dominated deltas. Here, tidal influence on river flow may extend up-river well beyond the distributary system. Many of the facies (tidal channels and flats) associated with tide-dominated deltas are similar to those discussed in the section on embayment facies. Tidal *sand ridges*, 10 km or more long, several kilometers wide and as much as 10 m high, are common in the funnel-shaped mouths of tide-dominated deltas. Where studied, these ridges display an upward coarsening from interbedded sand and mud to cross-bedded sand. Mud drapes and flaser bedding are common.

Fan deltas are a special type of delta that exists where an alluvial fan builds into a marine or lacustrine basin. Alluvial fans are constructed by a combination of fluvial processes and episodic debris flows; because they typically lie proximal to highlands, alluvial fans are generally composed of coarse sediment. Where waves are too small to redistribute this

sediment, it accumulates on the shoreline in the form of a *Gilbert delta*, with steep, nearly planar, foresets that extend to the floor of the adjacent basin. Such foresets may define a deltaic unit tens of meters thick. Sediment slides down the foresets in grain flows, in which the coarser material outruns the finer component. As a consequence, Gilbert deltas are likely to show an overall upward fining from their bases. Individual foreset layers, however, tend to display an upward coarsening normal to the stratification in response to the grain flow process that created them.

Gilbert deltas form in settings other than fan deltas, wherever coarse sediment is introduced into a basin with relatively low wave energy. Braided streams carrying a coarse sediment load commonly create Gilbert deltas where they encounter a shore. Alluvial fans differ from braid plains by containing debris flow deposits composed of unsorted layers of sand, mud, and gravel with little internal structure. Subaerial debris flows on fan deltas flows can extend across the strand line and compose much of the subaqueous part of the delta.

Sedimentary Facies of Coastal Embayments

Coastal embayments are bodies of water somewhat restricted from the open sea. They include river mouths, drowned river valleys, and lagoons or other bodies of saline water isolated from the open sea by a barrier island or spit. Estuaries are semi-restricted bodies of water in which river discharge

measurably dilutes the salinity. Lagoons may have no significant freshwater input.

Embayments are subject to a complex interplay of waves, tides, and river discharge. Of these processes, tides typically predominate. Generally, the limited wind fetch in embayments precludes the development of large waves. River discharge, an important factor in many embayments, need not be present. Dalrymple et al. (1992) provide a useful model of estuarine facies that recognizes an inner area dominated by fluvial processes, a central area of mixed energy in which both river flow and tidal currents are significant, and an outer area dominated by waves and tides.

Within embayments, specific sedimentary environments produce distinctive facies. In addition to the factors noted above, bay facies depend on the degree of subaerial exposure provided by the tides. Subtidal facies are never exposed, intertidal facies are exposed by the astronomical tides, and supratidal facies are inundated only during coincidence of high astronomical and high meteorological (storm surge or river flood) tides. This section addresses the most common sedimentary facies formed in coast embayments.

Tidal basins as used here are subtidal parts of a bay, which lack discrete tidal channels. As a consequence, tidal currents tend to be feeble, and the sediment largely undisturbed by physical processes. The substrate here is typically fine-grained and dominated by biogenic processes. Commonly the sediment is totally bioturbated. Mollusk shells are common, either as clasts or in situ. During periods of minimal sedimentation, articulated and disarticulated shells can form a pavement on the bay floor leading to discrete shell layers in the resulting deposit.

Tidal channels provide a focus for tidal flow within a bay. Their size ranges from tens of meters to kilometers across and meters to tens of meters deep. Their substrate ranges from gravel to mud depending on the nature of river influence and the texture of sediment available to reworking by tidal currents. Typically, tidal channels cut into older sediment or bedrock, and their floors are littered with coarse detritus:

shells, pieces of wood, mud clasts, and, today, human debris. Where tidal channels erode into a relatively consolidated muddy substrate, organisms, such as decapods may bore into the older material. The filling of these borings by channel-floor detritus generates a *Glossifungites* ichnofacies (MacEachern et al. 1992). Less cohesive substrates are likely to become colonized by bivalves, producing a thin interval of in situ shells below the base of a channel. Where sand is abundant, two- and/or three- dimensional dunes typically occupy a channel floor, producing trough or tabular cross-bedding. Otherwise, channel-floor deposits are likely to be thoroughly bioturbated, owing to slow rates of sediment accumulation.

Because tidal channels tend to migrate, their banks are either erosional or accretionary (Fig. 4). Accretionary tidal channel banks form a volumetrically important part of many ancient bay fills. Because accretionary banks are sites of deposition, internal physical structures are likely to be preserved. The nature of accretionary bank stratification depends greatly on sediment texture. Sandy banks are likely to preserve cross- bedding or ripple lamination. With increasing mud, the bedding style changes progressively from wavy (scattered clay drapes) to mixed (roughly equal quantities of sand beds and clay drapes) to flaser (mud encasing sand ripples) to laminated (mud with scattered sand laminae). Rhythmic stratification is common, owing to the regularity of tides or seasonal processes. Tidal channel bank deposits generally (but not invariably) show an upward fining. The migration of tidal channel banks produces large clinoforms that are evident in good exposures.

Tidal sand bars are ridges of sand within tidal channels. Such bars may be entirely subtidal or include both subtidal and intertidal components. Subtidal bars are 1–15 km long, have length to width ratios greater than three, and have a relief of as much as 20 m (Dalrymple and Rhodes 1995). The larger ones approach the size of tidal sand ridges of large open embayments and seaways (see Houbolt 1968). Sand waves (dunes) typically mantle the bar surfaces and internal

Coastal Sedimentary Facies,

Fig. 4 Components and stacking process of a mesotidal muddy tidal channel system

structure consists of trough and tabular cross-bedding. Where bars are less active, their internal structure is likely to consist of sets of cross-strata separated by bioturbated intervals, owing to low rates of aggradation and bedform migration. Larger bars commonly separate areas of flood- and ebbdominance. Like the tidal sand ridges in the North Sea, these ridges commonly are asymmetric whereby the steeper side faces in the direction of dominant sand transport. As a consequence the dip cross-bedding foresets is unidirectional in the direction of subordinate sand transport. Where tidal sand bars extend into the intertidal range, the vertical sequence likely to result if the bar were fully preserved consists of a lower subtidal and intertidal cross-bedded interval overlain by tide flat and salt marsh deposits (Dalrymple et al. 1990).

Intertidal flats are sandy or muddy areas of low relief that are alternately exposed and inundated by astronomical tides. Sedimentation rates are low and bioturbation predominates unless physical or chemical. A. Tidal channel floor composed of bioturbated shell and other lag; Numerous burrows/boring into firm ground beneath the channel floor form a *Glossifungites* ichnofacies; B. Tidal channel accretionary bank, composed of stratified mud and sand; C. Tide flat, underlain by bioturbated mud/or sand; D. Accretionary bank of runoff channel, composed of finely interlaminated sand and mud rich in organic detritus. Low-angle mud across-stratification; E. Supratidal flat, inundated only during combinations of high spring tides and meteorologic tides, such as storm surges. Underlain by laminated very fine sand/silt and mud. Numerous root or rhizome structures.

factors inhibit faunal colonization. An example is on flats exposed to very high tidal range (macrotidal flats). Here, the difference between high tide under neap and spring tidal conditions is sufficient to provide an upper flat that is only inundated during high-spring tides. This intermittent exposure precludes the development of a mature infauna, and stratification is preserved in the form of flaser, mixed, wavy, or lenticular bedding, depending on the proportion of sand and mud. Where mesotidal conditions (tidal range 2–4 m) obtain, the difference between high spring and neap tides is less and bioturbation prevails in nearly all of the flat sediment.

Most muddy tidal flats are crossed by narrow, dendritic *runoff channels* (tidal creeks), typically 1–2 m deep. Most runoff channels have an erosional and an accretionary bank. Sedimentation on the accretionary banks is very rapid and the sediment commonly displays laminae that reflect individual tides as well as neap and spring tidal cycles. Despite their meandering appearance, the rate of channel migration is slow, owing to the erosional resistance of the muddy substrate. Sediment that accumulates rapidly on accretionary banks is prone to slumping into the channel, where it is flushed out by the tidal currents. The limited channel migration produces muddy clinoforms or cross-strata, 1–2 m thick, characterized

by finely interlaminated sand, mud and organic detritus, and sporadic slump structures. Runoff channels on sandy tidal flats generally lack well-formed accretionary banks, and the associated distinctive facies.

Salt marshes are common on the upper part of many intertidal flats or marine delta plains (see Frey and Basan 1985). The substrate may be completely bioturbated or display faint rhythmic lamination. The organic content is typically high, and root or rhizome structures are typical. *Supratidal flats* lie higher still and are inundated only under combinations of high- astronomical and high-meteorological (river flood or storm surge) tides. Stratification, in the form of rhythmic alternations of silt and organic-rich mud, is typically crossed by numerous roots or rhizomes. Commonly the laminae form sets of several distinctive layers, probably deposited at successive high tides during a single meteorological event.

Bayhead deltas are common in estuarine bays. These may take the form of a small river delta, displaying a transition from muddy sediment in the most basinward, deeper parts to sandy sediment in the upper, river-dominated part. Fluvial or distributary channels cap the upper delta surface. The resulting deposit shows an upward coarsening. Evidence of tidal influences, such as tidal bundling or reversals in ripple-lamination or cross-bedding, can serve to distinguish this type of small delta from those produced by crevassing.

Coastal Sedimentary Facies, Fig. 5 Beach Ridges indicating progradation on the Nayarit coast of Mexico (After Curray et al. 1969). Each ridge marks a previous position of the coastline

In estuaries with a large tidal range, such as San Francisco Bay, the bay head delta comprises a complex of anastomosing channels without a clear deltaic form. In this setting, the bayhead delta consists of tidal channels that gradually transform landward into fluvial channels. The interface between salt and fresh water (head of the salt-water wedge) is typically very turbid and the site of rapid deposition from suspension. As with tide-dominated deltas on an open coast, the tidal influence on river flow may be expressed many kilometers upriver from the head of the salt-water wedge.

Washover fans are lobate accumulations of sand on the seaward side of lagoons, formed where storm waves breach a barrier and sweep sand into the adjacent lagoon (Leatherman et al. 1977). Bases are erosional, commonly marked by a shell lag. Internal structures include inversely graded planar lamination, ripple lamination, and climbing ripples, antidune stratification and, particularly at landward margins, landward-dipping cross-bedding. Tops of individual overwash accumulations can be bioturbated or contain rootlets.

Coastal Sedimentary Facies,

Fig. 6 Typical shoreface succession on a prograding pebbly, high-energy coast

Sedimentary Facies of Inlet Areas

Tidal inlets form a fluid interface between bays and the open coast (see Boothroyd 1985). Inlets may range from simple channels a few meters deep and tens of meters wide to complexes of channels and shoals more than 10 km or more across wide at the mouths of large embayments. Individual

channels in this setting may be tens of meters deep and hundreds of meters wide. Inlet sediment is mostly sand, and occurs in a setting where tidal flow is likely to be at its highest. As a consequence, inlet channels are typically floored by two- and three-dimensional dunes. Individual channels may be dominated by either ebb or flood tide. Lag deposits of shells and or pebbles (where the adjacent shoreface is gravelly) are

Coastal Sedimentary Facies,

Fig. 7 Typical shoreface succession on a prograding finer-grained, non-pebbly, high-energy coast

generally present, and may contain species representative of both open coast and bay. Trough and tabular cross-bedding and abundant burrows characterizes the resulting deposit.

Small inlets tend to migrate laterally along the coast, particularly where wave-driven longshore sediment transport is significant. Larger inlets may be more stationary, but interior inlet channels may migrate rapidly. In Willapa Bay, Washington, for example, a primary inlet channel, 25 m deep and 600–700 m wide, has moved laterally more than a kilometer in the past 50 years. Inlet fades in such a setting are

likely to consist of a lower part composed of cross-bedded sand produced in the primary channel overlain by the deposits of smaller tidal channels and wave- and tide-influenced shoals. Channel migration can produce clino-forms, the thickness of which depends on the depth of the channel. The lateral extent of inlet deposits depends on the degree of inlet migration. Extensive migration will generate laterally extensive inlet facies within a coastal succession.

Lobate bodies of sand, *flood tidal deltas*, form sandy ramps on the bayward side of many inlets. Where the tidal inlet

Coastal Sedimentary Facies,

Fig. 8 Stratigraphic succession produced in the upper part of a prograding river-dominated delta

migrates, flood tidal deltas may compose laterally extensive sand bodies along the seaward side of a lagoon enclosed by a barrier island. Initially these deltas form as a set of lobes building into the bay, covered by straight to sinuous two-dimensional landward-facing dunes (Hine 1975). As they mature, tidal flow is concentrated into channels, ultimately producing a low, seaward-facing ramp dissected by broad flood-dominated tidal channels (Boothroyd 1985). The resulting deposit is dominated by landward-directed trough

and tabular cross-bedding and contains internal erosional surfaces capped by shell lags.

Ebb tidal deltas form on the seaward side of inlets, where they are subject to the influence of both waves and tides. Off large embayments, these deltas may be quite large, exceeding 10 km in width and extending 5 km or more into the adjacent sea. Off smaller inlets on a transgressive coast, the deltas may form the nucleus of shoreface attached ridges (McBride and Moslow 1991). Flood- and ebb-dominated tidal channels

Coastal Sedimentary Facies,

Fig. 9 Vertical facies succession produced by migrating muddy tidal channel system. Thickness of sequence depends on depth of tidal channel and degree of subsequent erosion of upper part of succession

cross the shoal constituting the delta: typically the ebb flow is concentrated in the deeper channels. The combination of flood tidal flow and wave swash can produce a generally landward orientation to bed-forms on the delta platform (Boothroyd 1985). Upward-fining storm beds with erosional bases are common, particularly in the shallower parts of an ebb tidal delta.

Preservation of Coastal Sedimentary facies and Resulting Facies Successions

Thick accumulations of coastal facies typically reflect a record of fluctuating sea level superimposed on a setting of overall tectonic subsidence. The shore response to sea-level change depends on the rate of sedimentation. In general, the influx of sediment at the shore promotes progradation, whereby the additional sediment forces the shore to shift basin-ward. Today, most prograding open coasts are characterized by a series of beach ridges, each marking an earlier position of the shore (Fig. 5). The resulting accumulation conforms to Walther's Law, which holds that a vertical arrangement of related facies conforms to their lateral distribution at the time of deposition. Progradational successions show an upward-shallowing, produced as shallower water facies encroach over their deeper water counterparts. On deltaic or other open coasts, the result typically generates an upward-coarsening interval. Progradation also occurs on a smaller scale where a bayhead delta builds into an estuary, or a crevasse delta builds into a deltaic bay. Figures 6, 7, 8 show examples of progradational successions.

Fining-up facies successions are generated within bays and on deltas by the lateral migration of tidal or delta distributary channels. In these cases, the shallower parts of the system

consist of intertidal flats or salt marshes, or, with distributary channels, levees. Figures 8 and 9 show examples of fining-up successions produced by migrating channels.

Although progradation is the most common circumstance of preservation of coastal sedimentary facies, not all facies are preserved. Those associated with features that stand in relief above other, more landward, features are likely to be destroyed as progradation progresses.

Breaker bars, for example, are common features of many upper shorefaces (Fig. 2). During progradation, the seaward migration of the bar troughs that lie to landward erases much, if not all, of the bar. Similarly, distributary mouth bars have a limited potential for preservation. During the seaward migration of a distributary mouth system, distributary mouth bars are likely to be eroded and cannibalized by the distributary channel that created them. If that channel avulses, however, the associated bar may be preserved as a feature with limited lateral extent.

Where relative sea level falls during progradation a "forced regression" ensues. Wave erosion associated with the readjustment to a new, lower base level can create a "regressive surface of marine erosion". The amount of sediment removed by this erosion depends on the rate and degree of base level fall and prevailing wave energy. Commonly the surface marks an abrupt change from shelf to shoreface deposits.

Progradation may occur during relative sea-level rise, if the rate of sedimentation is sufficiently high. But commonly, a rise in base level is associated with deposition in the feeder systems. With the resulting reduction of sediment contributed to the coast, marine transgression occurs, whereby the shoreline shifts landward.

During transgression, some facies are likely to be preserved and others lost. During lowstands that commonly

Coastal Sedimentary Facies, Fig. 10 Transgressive erosion caused by the lateral translation of the shoreface (see Bruun 1962). None of the transgressive coastal facies are preserved, and the transgression is

recorded by an erosional ("ravinement") surface overlain by deeper water typically shelf) deposition

precede transgression, coastal rivers incise valleys near the coastline. Estuarine facies deposited in these valleys at the lowstand or during the initial rise tend to be largely preserved through a transgression.

A different situation prevails on the open coast. The natural product of waves and coastal winds is a shoreface and beach capped by a foredune ridge. In most wave-dominated settings, enough sand exists that a small rise in relative sea level is met by an upbuilding of the shore to a topographically higher position. Where a sea-level rise

causes a reduction in sediment input to the coast, a basin forms behind the beach ridge and a barrier island is created. Most present-day coasts fronted by barrier islands are in a state of transgression.

Barrier islands formed during transgression have a limited potential for preservation. The landward translation of a shoreface erases the deposits that lie landward from its base, leaving an erosional (*ravinement*) surface overlain by shelf facies (Fig. 10). Commonly this surface is the only preserved expression of a transgression.

Coastal Sedimentary Facies, Fig. 11 Transgressive succession produced in settings with rapid accommodation and adequate sedimentation. A lagoonal succession develops as the lagoonal facies are buried by

the landward-migrating barrier. It is capped by a “ravinement” surface overlain by shelf facies

Coastal Sedimentary Facies, Fig. 12 Vertical successions produced by preservation of transgressing lagoons. (a) High rate of accommodation. (b) Modest rate of accommodation

Under conditions of rapid accommodation and sufficient sediment supply, however, lagoonal facies are preserved (Fig. 11). These may occur in inverted succession, whereby the landward-most facies (lagoonal marshes and back-bay muds) are overlain by sandier deposits associated with the approach of the transgressing barrier and capped by tidal inlet facies just below the ravinement surface (Fig. 12a). The thickness and organization of these transgressive lagoonal deposits differs depending on the balance between accommodation and sedimentation. Although most are but a few meters thick, some can exceed 20 m. Most display a basal “bay-flooding surface” and a capping ravinement surface, although vigorous tidal currents and low rates of accommodation may in some places lead to the erosion of the lower part of the succession (Fig. 12b).

Coastal Soils

Charles W. Finkl
Coastal Education and Research Foundation, Asheville,
NC, USA

Introduction

The occurrence of soil in coastal zones is not a simple matter to resolve. Summarized coastal zones form a global perspective that only briefly indicates potential occurrence of soil in relation to coastal landforms, maritime climates, drainage, vegetation, and time available for formation. Increased understanding of coastal soils is, however, only possible from the purview of specific examples that illustrate soil distribution patterns in terms of sequences based on soil-forming factors of topography (toposequences), time (chronosequences), climate change (climosequence), and biological factors (biosequence). The conceptual frameworks for the models were initially postulated by Jenny (1941) and subsequently enhanced by various other researchers (e.g., Butler 1959, 1967; Runge 1973; Huggett 1975). The value of these sequential paradigms is that they provide visualization of complex interrelationships in a framework that clarifies and elucidates coastal-soil transition inland from the shore.

The models are relatively uncomplicated in young (Holocene), more or less uniform parent materials such as those which may occur in small deltaic areas, mangrove swamps, coastal alluvium, and dunes. Complications arise along most coasts because coastal fringes reflect polygenetic development where exceedingly old parent materials and associated soils may occur juxtaposed to incipient pedogenesis. *Environmental complexity* in coastal areas where there is rise and fall of relative sea level, stillstands and diastems, increase and decrease of sediment supply, delta progradation and retrogradation, alluvial channel avulsion, development of deltaic superlobes, chenier formation, climatic change, and so forth, is manifested in weathering zones and soils that provide clues to evolutionary sequences as does the stratigraphy and nature of the included materials. Examples of depositional sequences are reported by Davis (1978), Milliman and Meade (1983), Liu and Walker (1989), Less and Lu (1992), Roberts and Coleman (1996), Saito et al. (2000), and Yatsko (2000), among others, for a variety of coastal settings. Dune systems, including large eolianites, which can be just as complicated as deltaic sequences, often provide stratigraphy with intercalated Paleosols (e.g., Fairbridge 1950; Cooper 1966; Denny and Owens 1979; Hearty and Kindler 1997). Pedogenic inertia and persistence (e.g., Huggett 1975; Finkl 1980) is another problem where older soils (which in turn may be initial parent material for soil forming under new

environmental conditions) may occur in geomorphically young coastal landscapes.

Thus, coastal soils *sensu stricto* are often regarded as those soils that are derived from marine or estuarine parent materials that have recently been exposed subaerially to pedogenesis viz. acid sulfate soils, etc. Others might be related to coastal dunes, beach ridges, chenier plains, salt marsh, or upland freshwater marsh. The soils mostly range in age from late Holocene to early Pleistocene, reflecting a chronosequence that is geologically very young. This restricted point of view excludes many coastal sectors where soils of great age may be found, especially in the intratropical zones where coastal erosion may expose intensely weathered deposits as coastal cliffs in laterite (e.g., Hays 1967; Petit 1985; Retallack 1990; Wang 2003). Coastal soils *sensu lato* include a very wide range of possibilities as almost any kind of soil may occur in coastal zones. Fortunately, the possibilities are not endless and there is some order to apparent chaos of haphazard occurrence. Some clues as to potentialities for soil distribution patterns, at myriametric scales, on coasts may be gleaned from the morphological classification of coasts on the basis of plate tectonics (e.g., Inman and Nordstrom 1971) where tectono-physiographic settings limit the scope of pedogenesis. Trailing continental margins provide large expanses of coastal plain sediments, as occurring along the eastern seaboard of the United States, south of Washington, DC, where there are thick weathering sequences composed of residual oxidized materials and soils developed in alluvial, estuarine, and marine deposits (e.g., Markewich et al. 1986). In the vicinity of major rivers, especially on the southern coastal plain of the United States, major floodplains and deltas give rise to organic-rich soils. The coastal plains of southern Florida give rise to Holocene calcareous soils on slightly higher elevations whereas, lower poorly drained sites contain a suite of organic and muck soils related to Everglades, sloughs, swales, and other karst depressional areas that became infilled with fine-grained materials mixed with organic materials following the Holocene transgression (e.g., Gleason et al. 1984; Finkl 1994, 1995; Lodge 1994). Leading continental margins, such as that occurring along the mountainous and (strike-slip) faulted North American west coast where an oceanic plate is subducted below an overriding continental plate, provide a completely different set of tectono-physiographic conditions for soil development. Uplifted marine terraces contain soils of different ages, depending on the rates of uplift and number of terraces along the coast. Tsunami deposits, which are preserved in protected areas, provide allochthonous arenaceous parent materials for soils (Clague et al. 1999) that date back to the penultimate great Cascadia earthquake 1,000 years ago. Coastal valleys in Oregon and Washington often retain interesting stratigraphy, where earthquake-induced subsidence leads to the burial of alluvial and marsh soil profiles and the

development of younger soils in the new parent materials above (e.g., Nelson and Kashima 1993). Pedogenic environments along these kinds of tectonic coasts where there are active seismotectonic regimes, as in Greece (Maroukian et al. 2000) and throughout much of the Mediterranean region and elsewhere, are much more dynamic than the quiescent trailing margins.

Finally, there is the ultimately confounding situation where former coastlines are now stranded long distances from present shores. Many of these rocky shores (e.g., Johnson 1992; Libbey and Johnson 1997) provide parent materials for subsequent soil development (neopedogenesis of soil materials), but these occurrences can hardly be considered “coastal” in that pedogenesis is now unrelated to coastal factors of soil formation, other than coastal-marine parent material. Coastal Paleosols are, however, usually associated with modern as well as ancient coastlines whether at present sea level, emergent, or submerged. Emergent examples are best known and have been extensively studied along with Quaternary geomorphology and stratigraphy, for example, in Papua New Guinea (e.g., Bloom and Yonekura 1985), Barbados (e.g., Radtke 1989; Schellmann and Radtke 2001), Bermuda (e.g., Hearty et al. 1992), Bahama Islands (e.g., Hearty and Kindler 1997), Point Peron in Western Australia (Fairbridge 1950), Chile and Argentina in South America (e.g., Rutter et al. 1989), and many other coastal areas too numerous to mention. Notable within the present purview of coastal soils, however, is the study by Schellmann and Radtke (2003) who employ morphologic, pedostratigraphic, and chronostratigraphic assessments of marine terraces along the Patagonian Atlantic coast. Many of these studies were used for reconstruction of local sea-level history, including evidence in southwestern Western Australia for a higher relative mean sea level (MSL) during the Holocene (Fairbridge 1961; Playford and Leech 1977), but as discussed by Searle and Woods (1986) evidence for the ± 3 m oscillations proposed by Fairbridge can be elusive. Still other ancient shorelines, instead of experiencing terrestrial sequestration from the sea, are found as drowned relicts. Examples are reported from Hawaii (Fletcher and Sherman 1995), but there is no mention of included drowned soils.

Deltaic plains, such as the Mississippi River delta deposits, provide similar examples where constructive (alluvial accumulation, build up and soil formation) and destructive cycles (e.g., subsidence and drowning) present complex pedogenic environments that respond to fluvialdeltaic processes and longer-term base-level changes (Roberts and Coleman 1996). Callaway et al. (1997), studying sedimentary accretion rates on low tidal-amplitude sites along the Gulf of Mexico, found evidence that contravened previous hypotheses concerning the relationship between tidal range and marsh vertical accretion rates. They found that there was little correlation between mineral and organic matter accumulation

rates, with average organic matter accumulation rates showing less variation compared to mineral matter accumulation. There thus may be limits to annual rates of organic matter accumulation. Sediment addition is, however, clearly required for maintenance of coastal marsh soils (e.g., DeLaune et al. 1987, 1990).

There are many different soil classifications in use today throughout the world (see discussions in Finkl 1981), but none feature-specific sections on coastal soils per se. Rather than being perceived as a disadvantage, this situation is advantageous because soils occurring in coastal environments are hierarchically related throughout comprehensive soil classification systems and placed within continental or international schemes that facilitate reference and comprehension. Prominent among the major soil classifications are efforts by American, Australian, Canadian, French, German, Brazilian, and Russian soil researchers but the system employed here is the one adopted by the Food and Agricultural Organization FAO of UNESCO. The FAO system (FAO-UNESCO-ISRIC 1988; FAO 1991) is employed because it is specifically designed as an international system and because it provides a comprehensive inventory of world soil resources in the form of electronic databanks and maps. Although this is the primary organizing or categorical basis for discussing coastal soils, classes in other systems are sometimes equally valid (Spaargaren 2000) and they are sometimes referred to for ease of reference and also to avoid unnecessary complications that would arise from correlation with other systems. Local soil classification schemes often reflect regional or cultural bias in their geography and therefore international efforts are encouraged (e.g., Finkl 1982a, b). As already appreciated by many coastal researchers, they must be ambidextrous when dealing with coastal soil morphology, genesis, and classification. Unless otherwise stated, classificatory units referred to here belong to the international FAO system of soil classification, but similar and related terminology is also employed from the US soil classification system as applied in *Soil Taxonomy* (Soil Survey Staff 1975) and keys (Soil Survey Staff 1992). The following descriptions are based on FAO major soil groups.

Histosols

The major soil groups of Histosols (from Gr. *Histos*, tissue) include a wide variety of peat and muck soils that range from moss peats of the boreal tundra, moss peats, reeds/sedge peats, forest peats of the temperate zone, and mangrove and swamp forest peats of the humid tropics (Spaargaren 1994; Inubushi et al. 2003). Histosols are unlike all other soils in that they are formed in and by “organic soil material” with physical, chemical, and mechanical properties that differ strongly from those of mineral soil materials. They develop in

conditions where organic materials are produced by an adapted (climax) vegetation, and where biochemical decomposition of plant debris is retarded by low temperatures, persistent waterlogging, extreme acidity, oligotrophy and/or the presence of high levels of electrolytes from organic toxins. Organic soil material contains more than 12% organic carbon by weight (20% OM). The diagnostic horizons for Histosols are the histic and folic horizons. Other diagnostic horizons used to separate soil units in Histosols are termed sulfuric, sulfidic, and salic. The combination of specific environmental conditions, composition of the organic soil material, and degree of decomposition produces six soil units that include: Gelic Histosols (permafrost occurs within 200 cm of the soil surface), Thionic Histosols (there is a sulfidic or sulfuric horizon starting within 125 cm of the surface), Salic Histosols (there is a Salic horizon starting within 50 cm of the surface), Folic Histosols (folic horizon present), Fibric Histosols (more than two-thirds of the organic soil material consists of recognizable plant material), and Haplic Histosols (other units).

Histosols form where the rate of accumulation of plant debris exceeds the rate of its decay (e.g., Nyman et al. 1993). In practice, Histosols occur where microbial decomposition of plant debris is impaired by: cold temperatures, excessive wetness, salts or other toxins, and severe aridity or oligotrophy. Histosols under the permanent influence of groundwater, unless artificially drained (e.g., “low moor peats”) occur in low-lying positions in fluvial, lacustrine, and marine landscapes, mainly in temperate regions but also to limited extents in the tropics. Other soils occurring in the same environment include Fluvisols, Gleysols and, in coastal regions, Solonchaks (e.g., adjacent to coastal mangrove peats). In lacustrine landforms and in coastal marsh embayments, Histosols may be associated with Vertisols, such as that occurring on the Texas Gulf Coastal Plain (e.g., Stiles et al. 2003). Oligotrophy and prolonged wetness are primarily accountable for the low decay of organic debris. In the wet tropics (mainly the Indonesian region surrounding the Sunda Flat), their formation is conditioned by high rates of organic matter production from the climax forest vegetation. Change in use of tropical peatlands can affect the decay rates of organic matter and production of methane and nitrous oxide gases viz. conversion from secondary forest peatland to paddy fields, as reported for Kalimantan in Indonesia (Inubushi et al. 2003). In addition to landuse change as a forcing function for pedogenic succession, similar migration of soil properties are associated with tidal inundation along transgressive coastal areas such as around the Chesapeake Bay on the eastern US coastal plain. Hussein and Rabenhorst (2001) report, for example, pedogenic transformation of Ultisols to Alfisols and eventually to Histosols in response to sea-level rise, based on changes in sodium adsorption ratios and exchangeable sodium percentages. Salinization and alkalization

processes as a function of tidal inundation frequency across low-lying coastal landscapes produce lateral changes in pedogenic properties that ultimately relate to different profile characteristics and classification of soils. Lateral pedological linkages exist with a variety of other soil groups, including Podzols, Fluvisols, Gleysols, Cambisol, and Regosols.

The global extent of Histosols is about 275 million ha (FAO 1991) (Table 1), roughly half of which are located in the Arctic zone, onethird in temperate lowlands, and one-sixth in tropical lowlands (Spaargaren 1994). An example of the latter case is the subtropical Florida Everglades, which constitute the largest single body of Histosols in the world (Stephens 1956, cited in Amador and Jones 1995). A large area of cold region organic soils occurs on the southern and southwestern subArctic margins of Hudson Bay (Manitoba, Ontario, Quebec) and around Great Bear Lake (Northwest Territories) in Canada. Here, Cryic Fibrisols (with frozen subsurface) occupy about 171,715 km² of coastal plain (Clayton et al. 1977).

In lower latitude coastal areas, continually rising sea level has caused brackish or saline waters to engulf drowned river valleys (rias) or to extend over formerly upland soils. This has led to the formation of coastal marsh Histosols in several geomorphic settings (Darmody and Foss 1979). As sea levels continue to rise, marsh margins are pushed landward and the organic materials continue to thicken so that the older and deeper Histosols generally exist nearer the open water (e.g., Nyman et al. 1993; Rabenhorst 1997). Although distant from high-latitude glacial activity, coastal Histosols at lower latitudes were impacted by glacio-eustatism (e.g., Rabenhorst and Swanson 2000). During the glacial maximum (~20,000 year BP) when large quantities of water were bound in glacial ice, eustatic sea level was at least 150 m below present MSL. Deglaciation cycles caused sea level to rise at such a rapid rate (~10–20 mm a⁻¹) that initially vegetation could not colonize tidal regions. Approximately 3,000–5,000 years ago, sea-level rise slowed so that marsh vegetation became established and organic parent materials began to accumulate (Bloom and Stuvier 1963; Redfield 1972). As sea level rose, organic materials accumulated in Histosols so that coastal marshes and mangroves generally accreted at about the same rate. Peat accretion in coastal areas presently ranges from 3 to 8 mm a⁻¹, which is much higher than in non-coastal regions. The highest rates of sea-level rise may, however, be too great for marsh systems to maintain and some areas suffer marsh loss and degradation (e.g., Huiskes 1990; Nyman et al. 1993; Boesch et al. 1994) where Histosols are eroded, degraded (e.g., Mendelssohn and McKee 1988) or drowned. Loss may also occur in response to subsidence (primarily as microbial mineralization of soil organic matter), such as in areas of the Florida Everglades where drainage of coastal wetlands (Everglades marsh) (Finkl 1995) has exposed organic soils subaerially (Stevens et al. 1984) and

Coastal Soils, Table 1 Main kinds of soils occurring in coastal areas, based on a world reference base for soil resources, indication the different types of soil cover in relation to landscape features and associated linkages with related soils

Soil group (FAO) ^a	Area (×10 ⁶ ha) ^b	Major subdivisions ^c	Associated soils ^d	Lateral linkages or intergrades ^e	Landscape position, climate, drainage, topography, or parent materials
Histosols	275	Gelic, Thionic, Salic, Follic, Fibric, Haplic Histosols	Fluvisols, Gleysols, Solonchaks, Vertisols	Podzols, Fluvisols, Gleysols, Cambisols, Regosols	Low-lying positions in fluvial, lacustrine, and marine landscapes. Solonchaks often adjacent to coastal mangrove peats
Anthrosols	NA	Hydragric, Irragic, Cumulic, Hortic Anthrosols	Border most of the major soil groups where soils have been strongly influenced by man	Includes coastal archaeological sites	Old cultivates sites, excluding paddy soils, on coastal plains, river valleys, deltas, etc.
Leptosols	1,655	Lithic, Cryic, Skletic, Rendic, Mollic, Umbric, Dystric, Eutric Leptosols	Regosol, Cambisol, Podzol, Calcisol, Luvisol, Histosol, Anthrosol	Wide range of intergrades	Tropics to polar tundra, coastal lowlands to mountains
Cryosols	1,800	Histic, Thixotropic Cryosols	Histosols, Gleysols, Stagnosols, Cambisols	Gelic or cryic units of Histosols, Gleysols, Podzols, Planosols, Glossisols, Stagnosols, Cambisols	Arctic coastal plains of NE Eurasia, Alaska, Yukon, and NW territories of Canada; islands of Siberian, Beringian, and North American sectors of the Arctic Ocean; coastal Greenland
Fluvisols	350	Thionic, Salic, Vertic, Mollic, Calcaric, Umbric, Dystric, Eutric	Cambisols, Regosols, Arenosols, Leptosols, Gleysols, Solonchaks	Arenosols, Cambisols, Fluvic Gleysols, Salic Fluvisols (intergrade to Solonchaks)	Large deltas and fans viz., Ganges, Mekong, Mississippi, Niger, Po, Rhine; major river floodplains; coastal barriers; tidal flats
Solonchaks	260–340	Gleyic, Stagnic, Mollic, Gypsic, Calcic, Sodid, Haplic Solonchaks	Chlorida and sulfate soils	Salic Fluvisols, Thionic Fluvisol-Solonchak intergrades	Coastal salt lakes, lagoons, pans; chloride facies-soils of marine origin under mangrove; neutral chlorido-sulphate soils-of marine origin but enriched by sedimentary gypsum deposited by rivers; acid sulphate soils-soils of marine origin under mangrove as in Gambia, Senegal, Guinee Bissau
Gleysols	720	Cryic, Thionic, Plinthic, Arenic, Mollic, Umbric, Fluvic, Calcic, Haplic Gleysols	Leptosols, Vertisols, Fluvisols, Solonchaks, Stagnosols, Histosols, Regosols	Histi-Mollic, Histi-Umbric Gleysols, Fluvic Gleysols (intergrades to Fluvisols)	Sandy to loamy (sometimes clayey) textural classes of parent material on alluvial, fluvial, fluvio-glacial deposits in riverine or coastal areas. Common in depressional and organic-rich coastal areas; for example, Arctic coastal plains, coastal Alaska; Florida Everglades
Podzols	485	Gelic, Gleyic, Stagnic, Humic, Duric, Umbric, Cambic, Haplic	Histosols, Gleysols, Cryosols, Cambisols, Ferralsols, Planosols, Glossisols	Podzol-Histosol-Gleysol sequences, Cambisol-Podzol sequence	Sandy deposits affected by illuviation and cheluviation, boreal climatic zone, coniferous vegetal cover, temperate and tropical wet climatic areas. For example, NE and NW coastal Canada, Scandinavia, NW coastal Russia; coastal plain of Florida; southwestern Australia; coastal Indonesia
Sesquisols	60	Petric, Aeris, Albic, Stagnic, Humic, Eutric, Haplic Sesquisols	Ferralsols, Alisols, Acrisols, Lixisols	Found in association with Gleysols and Stagnosols in areas conditioned by hydromorphy; with Ferralsols, Alisols, Acrisols, and Lixisols in better drained positions in the landscape	Usually ancient landsurfaces truncated by modern coastal erosion or in close proximity to the sea; older coastal plains; for example, western Africa, western India, Mekong catchment,

Coastal Soils, Table 1 (continued)

Soil group (FAO) ^a	Area ($\times 10^6$ ha) ^b	Major subdivisions ^c	Associated soils ^d	Lateral linkages or intergrades ^e	Landscape position, climate, drainage, topography, or parent materials
					northern and southwestern Australia, eastern Amazon region
Ferralsols	750	Humic, Geric, Gibbisc, Lixic, Rhodic, Eutric, Plinthic, Gleyic, Haplic Ferralsols	Cambisols, Acrisols, Nitisols, Gleysols, Planosols, Arenosols, Sesquisols	Intergrades to Cambisols, Acrisols, Nitisols, Gleysols, Planosols, Arenosols, Sesquisols	Mid- to end-Tertiary peneplains; for example, Brazilian Shield, French Guyana, Senegal, Madagascar, northern and SW Australia; extreme tropical and subtropical weathering
Planosols	130	Gelic, Vertic, Histic, Mollic, Umbric, Dystric, Eutric Planosols	Vertisols, Acrisols, Luvisols	Stagnic Solonetz, Albic Sesquisols, Stagnic Gleysols; related soils with abrupt textural change but insufficiently wet to show reduction by surface water would fall into Luvisols, Lixisols, Alisols, Acrisols	Low-lying, nearly level fluvial or marine terraces, depressional lands on coastal plains, including wetland rice paddies; most extensive in climes with a strongly seasonal variation in rainfall that results in intermittent saturation and reduction of upper soil horizons
Solonetz	135	Gleyic, Stagnic, Salic, Albic, Mollic, Gypsic, Calcic, Haplic Solonetz	Linked through sodic units to Vertisols, Solonchaks, Gleysols, Calcisols	Salic Solonetz, Sodic Solonchaks; through sodic properties in Vertisols, Solonchaks, Gleysols, and Calcisols; with Gleysols and Stagnosols through the Gleyic and Stagnic Solonetz soil unit	Solonetz landscapes are governed by microrelief, waterlogging at the surface, and salinity in the profile; lake terraces, river deltas, depressions along liman coasts; Rio de la Plata deltaic plain in Argentina; coastal South Australia and coastal southeastern Western Australia
Calcisols	800	Petric, Luvic, Sodic, Cambic, and Haplic Calcisols	Vertisols, Solonchaks, Gleysols, Solonetz, Luvisols	Calcic Gleysols, Calcic Gypsicisols, Calcic Luvisol	Arid coastal regions viz. Baja, California; Patagonia and Argentine Pampa; coastal Atacama; Namibia; coastal northern Africa; Nullarbor Plain in Western Australia and coastal plain in South Australia
Alisols	>100	Plinthic, Gleyic, Humic, Vertic, Ferric, Chromic, Luvic, Haplic Alisols	Ferralsols, Nitisols, Acrisols, Lixisols, Vertisols, Cambisols	Vertic Alisols, Alic Nitisols, Alic Acrisols; facies of other highly weathered soil units in intertropical regions	Coastal plain in southern USA; parts of intertropical coastal India, Africa, and northern Australia
Acrisols	>900	Plinthic, Gleyic, Humic, Arenic, Albic, Ferric, Haplic	Lixisols, Luvisols, Alisols, Nitisols, Glossisols	Planosols, Lixic Ferralsols, Arenosols, Regosols, Cambisols	Ancient shield landscapes, in tropical regions, that are truncated by coastal plains or marine erosion; coastal plain is southeastern USA, Caribbean Central America coastal lowlands, Orinoco deltaic plain, western Africa, Southeastern Asia, Indonesia
Luvisols	650	Gleyic, Albic, Vertic, Calcic, Ferric, Chromic, Dystric, and Haplic	Alisols, Lixisols, Acrisols, Nitisols, Glossisols, Solonetz	Luvic Chernozems, Luvic Gypsicisols, Luvic Phaeozems, Luvic Calcisols, Luvic Arenosols	Humid to subhumid temperate regions of western Europe (Belgium, The Netherlands, coastal Germany), parts of the Mediterranean region, southern Australia (extreme southwestern Western Australia, central South Australia), eastern Indian coastal regions, Sri Lanka
Lixisols	435	Plinthic, Gleyic, Humic, Arenic, Albic, Ferric, Haplic	Nitisols, Alisols, Acrisols, Luvisols, Glossisols	Ferralsols, Regosols, Cambisols, Luvisols	On stable shield landscapes in tropical regions; in seasonally dry tropical, subtropical, and warm temperate regions, on Pleistocene and older surfaces (including Alluvial fans); coastal savanna regions

Coastal Soils, Table 1 (continued)

Soil group (FAO) ^a	Area ($\times 10^6$ ha) ^b	Major subdivisions ^c	Associated soils ^d	Lateral linkages or intergrades ^e	Landscape position, climate, drainage, topography, or parent materials
Cambisols	1,500	Gelic, Gleyic, Vertic, Fluvisol, Mollic, Calcaric, Ferralic, Dystric, Chromic, Eutric Cambisols	Luvisols, Ahsols, Acrisols, Lixisols, Nitisols, Ferralsols	Regosols, Leptosols, Gleysols, Fluvisols, Acrisols, Sesquisols	Islands (Puerto Rico, Madagascar, New Zealand, Papua-New Guinea); Atlantic Spain and Portugal; Mediterranean Spain, France, western Italy, Turkey; southeastern Australia
Arenosols	900	Leptic, Albic Protic, Gypsic, Calcaric, Luvic, Ferralic, Cambic, Haplic	Regosols, Leptosols, Cambisols, Gleysols, Fluvisols	Acrisols, Lixisols, Ferralsol, Planosols, Histosols, Anthrosols, Solonchaks, Regosols, Leptosols, Calcisols	Dry tropical and temperate interior regions, but some coastal areas in western Africa, western Madagascar, and northwestern Australia
Regosols	260	Gelic, Anthropic, Tephric, Gypsic, Calcaric, Dystric, Eutric	Arenosols, Leptosols, Gypsisols, Ferralsols, Cryosols	Found in all landscapes of the world; intergrades and extragrades may develop into many other soils, depending on the most important soil forming factor(s)	Shallow, weakly developed mineral soils in the initial stages of soil formation; all coastal landscapes

Notes: Compiled from Spaargaren (1994)

^aBased on the FAO World Reference Base (WRB) major soil groups, compiled and revised from the FAO/UNESCO International Reference Base for Soil Classification and the Legend of the Soil Map of the World (FAO-UNESCO-ISRIC 1988)

^bTotal area (in millions of hectares) is based on estimated WRB worldwide occurrence of the soil group; coastal occurrences are a smaller subset of unknown areal extent

^cMajor subdivisions that are proposed to separate the soil groups on the basis of diagnostic properties. Not all of the soil units listed occur in coastal areas as major soils, but they are listed for completeness, where they may be found in specialized environmental situations

^dOther soil groups that occur in the same general area or environment; soil groups were not differentiated on the basis of climate in order to keep the number of units manageable. Differences in topography, drainage, and other diagnostic properties and materials result in a range of different soil groups that occur in close geographic proximity to each other

^eLateral linkages are commonly intergrades that merge soil units in time and space. These units also reflect the spatial integration of soil properties in the coastal landscape where differences in the factors of soil formation (i.e., topography or relief, time, drainage or hydrology, organics, parent or initial materials) may lead to rapid lateral changes in soil units. Relief, drainage (or lack thereof, salt spray, or influence of tidal waters), parent materials (terrestrial versus marine sediments), and time (especially in regard to young soils forming in marine sediments) are particularly relevant to coastal soil distribution patterns

their surface elevations may decrease by as much as -2.5 cm a^{-1} .

The Florida Everglades is the largest continuous sedge moor outside of the Pleistocene glaciated area of the United States (Gleason et al. 1984). The expansive coastal wetlands and freshwater marsh of southern Florida are a result of the very slow relative rise of sea level during the past 3,200 years (average rate of 4 cm per century) (Spackman et al. 1966; Wanless et al. 1994). A large number of coastal sediment bodies in southern Florida were initiated or stabilized between 3,300 and 3,000 year BP and again approximately between 2,300 and 2,500 year BP (Wanless et al. 1994). The origin and development of those coastal and shallow-marine carbonate and clastic sediment bodies is dependent on the interactive roles and timing of sea-level changes, climatic fluctuations, storm influences, vegetative colonization, preexisting topography, and provision of detrital (input or recycled) siliciclastic and carbonate sediment. Of these, the rate of sea-level rise was the primary control on the clastic, carbonate, and organic sediment bodies of southern Florida.

As one of the largest marshes in the world, the Everglades peat deposits are commonly differentiated into subtypes

based on compositional variation, thickness, and degree of weathering. Water is required for the formation of peat soil because it restricts atmospheric oxygen from the soil; without oxygen, microorganisms cannot decompose dead marsh plants as fast as they accumulate. Ever-thicker deposits of peat are deposited until an elevation is reached where the surface dries enough that oxygen-dependent decay (the opposing aerobic process), or fire, prevents accumulation (Lodge 1994). Freshwater peats of the Everglades merge southwards with mangrove peats on the tidal plain fronting Florida Bay. Occupying more than 400 ha of marshland, the Everglades Peat forms from degraded saw grass in long-hydroperiod habits. It is the most abundant peat occurring in the Everglades Basin. The Loxahatchee Peat, covering about 29,000 ha, occurs in deeper marsh areas and contains less saw grass remains and more evidence of slough vegetation such as the roots, rhizomes, leaves, and seeds of water lilies. Very poorly drained organic soils of the Everglades usually have a surface layer of black muck (sapric material-organic material that is too finely divided for identification of plant remains) that overlies black or reddish-brown muck subsoils that in turn rest on sand, limestone bedrock, or other materials

(McCollum et al. 1978). The term *muck* refers to highly disintegrated peat soils that are composed of more mineral than organic matter (see discussion in Brown et al. 1990). *Marl* is the product of periphyton. During the dry season, the organic material (dead algae) in the periphyton mass oxidizes, leaving the calcium carbonate particles as a light-colored soil. Marl is descriptively called *calclitic* mud and is the main soil of the short-hydroperiod wet prairie habitats near the margins of the southern Everglades where bedrock lies close to the surface (Lodge 1994). Marl and peat soils are opposites, requiring aerobic and anaerobic soil conditions, respectively. Peat cannot accumulate in shorter hydroperiod marshes where marl persists, and acid conditions within a peat soil dissolve marl and prevent its accumulation. However, there are large areas in the northern Everglades where a thick layer of marl underlies peat. This occurrence is evidence that the hydroperiod increased substantially in those areas as the Everglades ecosystem evolved. Much of the Everglades region is flooded during the summer rainy season, which is a natural process essential to the health of this wetland. Many areas of urban development, especially on the coastal plain of southeast Florida, occur on former Everglades (wetlands that were drained as part of reclamation programs) (Finkl 1995) where Histosols have been stripped away and building sites “demucked” and filled with dredged materials. The region is, however, prone to returning to its natural wetland condition during high rainfall events making localized sectors of the region susceptible to flooding (Finkl 2000).

Acid Sulfate Soils

Acid sulfate soils occupy an area of some 24 million ha worldwide where the topsoil is severely acid or will become so if drained (Ritsema et al. 2000). An equal area of these soils may be thinly covered by peat and nonsulfidic alluvium (van Mensvoort and Dent 1997). Acid sulfate soils are typically associated with mangrove forests that once covered 75% of the coastlines in tropic and subtropical countries (Quarto and Cissna 1997). Estimates of the extent and distribution of acid sulfate soils suffer, however, from the lack of field surveys, few reliable laboratory data, and from variable definition. More significant than their areal extent is their location where they are concentrated in otherwise densely settled coastal and floodplains, mostly in the tropics, where development pressures are intense with few suitable alternatives for expansion of farming, or urban or industrial development. Two-thirds of the known extent is in Vietnam (e.g., Mekong River Delta), Thailand, Indonesia, Malaysia, western Africa (Senegal, Guinea Bissau), northern Australia, and on coastal plains in southern China (e.g., Pearl River Delta). By far, the largest use of acid sulfate soils is for rice cultivation viz. the Balanta system in western Africa (van Ghent and Ukkerman

1993) where land is ridged annually to a height commensurate with the expected freshwater flood of the rainy season. The ridging and annual turning speedup removal of soluble toxins from the surface soil, but the system is declining because of the heavy labor demand and low financial returns.

Acid sulfate soils exhibit enormous spatial variability that is tied to the dynamic estuarine, deltaic, and flood plain environments in which they occur. Figure 1 shows typical colonization by mangroves into carbonate intertidal flats that will eventually become sites for accumulation of organic debris derived from the mangroves. Organic-rich muds will eventually develop and be accompanied by pedogenesis. Significant spatial variability occurs at myriametric scales from pyrite-plugged pores to the fine-grained soil matrix to infield, local, and regional soil patterns (Dent 1986). Remote sensing is widely used in tropical, tidal environments because surveys are arduous and difficult due to mosquitoes and crocodiles. Acid sulfate soils also exhibit significant temporal variability that is associated with their defining characteristics of acidity and related toxicities. Almost uniquely, acid sulfate soils export their problems in drainage and floodwaters.

Evident in acid sulfate soils are patterns related to sedimentary history viz. the common distinction between highly sulfidic, unripe clays or peat in backswamps and ripper, coarser textured soils, or even calcareous soils on levees and creek fillings. Soil patterns are not always visible at the surface because present landforms and vegetation may be only partly and indirectly related to the environment of sulfide accumulation. The area may, for example, have been buried by peat or nonsulfidic alluvium, fresh waters may have succeeded brackish, and new plant communities have replaced prior ones.

Sulfidic soils that oxidize and generate H_2SO_4 when drained are referred to as *potential acid sulfate soils* (Wang and Luo 2002). If they have been drained and are generating H_2SO_4 , they are called *raw acid sulfate soils*, but if they have passed through the acid-generating phase but remain severely acid, they are referred to as *ripe acid sulfate soils*. Sulfidic materials include marine and estuarine sands and clays, gyttja in brackish lakes and lagoons, and peats that originally formed in fresh-water but which have been inundated subsequently by brackish water. The common factors are: (1) supply of organic matter, (2) severely reducing conditions caused by continuous water logging, and (3) a supply of SO_4^{2-} , usually from tidewater that is reduced to sulfides by bacteria decomposing organic matter, and (4) a supply of Fe from the sediment for the accumulation of iron sulfides which make up the bulk of reduced S compounds. These conditions are fulfilled in tidal swamps and salt marshes where thick deposits of sulfidic clay have accumulated in concert with Holocene sea-level rise (e.g., Pons and van Breeman 1982; Dent and Pons 1995). As sedimentation raises the soil surface

Coastal Soils, Fig. 1 Initiation of mangrove foothold on intertidal marine platform on Eva's Cay, west (bank or leeward side) of Salt Pond on Long Island land, Bahamas. Carbonate muds and micritic sediments show initial phases of biochemical weathering as mangroves colonize the area. Accumulation of organic debris derived from the mangroves eventually results in dark coloration of chemically reduced muds. Mangrove soils often show light (thin bands) and dark (thick bands) lamination in the profile because pedogenesis is interrupted by

storm waves that deposit new unweathered materials on top of pedogenically altered materials. This mangrove mud is minimal as the stand is only just taking a foothold; older, well-developed mangrove forests such as that occurring in the world's largest estuarine delta (2,600 km²) along the Indian coast southeast of Calcutta in West Bengal as Sunderbans (beautiful forests) and many other tropical coastal locations feature thick organic-rich profiles.

above MSL, topsoil accumulates under better drainage as a nearly ripe, mottled layer that contains little or no sulfide. Sulfidic clays may be buried by peat or nonsulfidic alluvium where freshwater conditions succeed brackish water.

Reclamation and drainage of sulfidic soils causes dramatic changes. When insufficient carbonate is present to neutralize the H₂SO₄ generated by oxidation of sulfides, extreme acidity develops within weeks or months. Raw acid sulfate soils, characterized by a pH <3.5, contain jarosite but frequently display a black subsoil as some of the SO₄²⁻ generated by drainage is reduced to FeS deeper in the profile. Experiments on acid sulfate soils in the southern coastal regions of Guangdong, China, for example, show that the sulfur content of acid sulfate soils is 2–6 times higher than that of coastal Solonchaks and 3–9 times higher than that of paddy soil (Wang and Luo 2002). The potential acidity is 2–3 times higher than the actual acidity and the amount of lime required to correct the potential acid ranges from 143.5 t ha⁻¹ to 2,687.5 t ha⁻¹.

Acid sulfate soils cause on-site problems and also in adjacent areas with the latter attracting attention (Dent 1986). On-site problems include Al toxicity in drained soils, Fe and H₂S toxicity in flooded soils, salinity, and nutrient deficiencies. Engineering problems include: (1) corrosion of steel and concrete, (2) uneven subsidence, low bearing strength, and fissuring leading to excessive permeability of unripe soils, (3) blockage of drains and filters by

ochre, and (4) difficulties of establishing vegetation cover on earthworks and restored land. Off-site problems stem from drainage effluents, earthworks, excavations, and mines. The acid drainage waters carry Al released by acid weathering of soil minerals and heavy metals that are released by oxidation of sulfide minerals. Episodic release of toxic drainage waters may occur, for example, at the onset of the wet season after a period of low water table during which oxidation has taken place.

Gleysols

Gleysols (from Russian local name *gley*, mucky soil mass) or soils with gleyic properties are permanently wet and reduced in the subsoil (e.g., Schlichting 1973), and periodically to permanently wet in the topsoil (Spaargaren 1994). Mainly found in periodically poorly drained depressions, valleys, and low-lying coastal areas, the solum is either mottled (in case of temporary aeration) or has colors reflecting reduction. These redoximorphic features form under the influence of poorly to welldrained groundwater regimes. Typical gleyic soils are classified as Gleys or Groundwatergleys in many European systems of soil classification (e.g., Austria, Germany, France, Switzerland, United Kingdom), although in the German classification the periodically flooded soils of coastal regions are separated

as *Marschböden* from normal Gleysols. Gleysols are found in nearly all climates, from perhumid to arid conditions, and cover an area of almost 720 million ha (FAO 1991) (Table 1). In regions with permafrost (e.g., Arctic Canada, coastal plain of northern Siberia), Cryic Gleysols occur in association with Cryosols and Gelic Histosols. In the lowlands of the temperate latitudes, they are formed in alluvial sediments associated with Fluvisols near riverbeds in coastal areas, and with Histosols. In the humid tropics, they are found in valleys associated with Acrisols, Lixisols, Nitisols, Alisols, or Ferralsols.

Gleysols (Eutric Gleysols, FAO) are a dominant soil of Canada, with major areas occurring in the subArctic and Hudson Bay Lowland (Clayton et al. 1977). Most Gleysols occur on nearly level to undulating topography, particularly where associated with lacustrine, alluvial, or marine deposits that are moderately calcareous and loamy in texture. Cryic Gleysols occur throughout the entire Arctic region of northern Canada, including the Arctic islands extending from the Labrador coast to the Yukon-Alaska border. About 37,698 km² or 0.4% of Canada is mapped as dominantly Cryic Gleysols; these areas occur in the Northwest Territories and Yukon. They are found within the Mackenzie Delta and the Arctic Coastal Plain. Gleysols are often spatially associated with Podzols and Luvisols.

Anthrosols

These soils result from human activities that produce profound modification or burial of the original soil horizons. In the 1988 Revised Legend of the Soil Map of the World (FAO-UNESCO-ISRIC 1988), these are "... soils in which human activities have resulted in profound modification or burial of the original soil horizons, through removal or disturbance of surface horizons, cuts and fills, secular additions of organic materials, long-continued irrigation, etc. ..." Implicit in this general definition is the recognition of a distinct set of anthropedogenic processes that are associated with characteristic anthric diagnostic horizons. Anthropogenic soil materials that result from anthropogeomorphic processes are better considered as "non-soil," unless they are subjected to a sustained period of pedogenesis (Spaargaren 1994). Many different soil classification systems from around the world make provisions for these kinds of soils. Continuous cultivation of paddy soils often produces a hydric horizon that also includes redoximorphic and illuviation features in the subsoil. Many Anthrosols occur in coastal deltaic environments, especially in Southeast Asia and Indonesia. The Mississippi Delta region in the United States contains extensive areas of Anthrosols that are now subject to drowning by relative sea-level rise and contribute to the land-loss problem in coastal Louisiana (Boesch et al. 1994).

Leptosols-Entosols, Regosols, Lithosols, etc.

The name Leptosols (from Gr. *leptos*, thin) is used in the FAO *World Reference Base for Soil Resources* (Spaargaren 1994) for shallow soils overlying hard rock or highly calcareous material, and soils that have, by weight, less than 10% fine earth material. Leptosols occupy more than 1,655 million ha from the tropics to polar tundra (Table 1). Different names have been used in reference to these kinds of shallow, rocky soils. The term *Lithosol* was applied by Thorp and Smith (1949) to denote azonal soils having an incomplete solum or no clearly expressed soil morphology and consisting of freshly or incompletely weathered mass of hard rock or hard rock fragments. *Rankers* were defined as soils that have a dark-colored surface horizon, rich in organic matter with a low base status that is overlying unconsolidated siliceous material exclusive of alluvial deposits or hard rock. The name *Rendzina*, as first used by Sibirtzev (1901), was originally assigned to intrazonal soil on calcareous rocks. *Regosols* were first defined by Thorp and Smith (1949) as an azonal group of soils consisting of deep unconsolidated rock (soft mineral deposits) in which few or no clearly expressed soil characteristics developed.

Leptosols represent the initial phases of soil formation and as such, they are of great significance because they are the forerunners of the young or weakly developed soils of other units. These soils occur in landscapes where deposition or erosion, resistant bedrock, inert parent material, saturation, or human activity was limited normal pedological development. These soils commonly form on mountains, sand dunes, flood plains, and riverine lunettes, and coastal plains. In northern Canada, for example, Cryic Orthic Regosols in Arctic Lowlands commonly occupy gently undulating coastal plains developed on stony or sandy glacial till and marine deposits and occupy upwards of 1,305,423 km² (Clayton et al. 1977), but not all of this area is coastal. Parent material lithology is a factor that may inhibit pedogenesis where resistant bedrock, for example, increases runoff and erosion, and thereby decreases weathering. These soils also form in sandy parent materials that have an abundance of rock fragments. When parent materials consist of quartzitic sands without coarse fragments, such as in many sand dunes, profile development is also retarded.

Coastal dunes are built of beach sand blown onshore. Calcareous sand may give rise to calcareous eolianite, as on the coast of western Victoria (Australia), southwestern Western Australia, Bermuda, and the Bahamas. Quartz sand dunes are common in eastern Australia and grew particularly large during the last Ice Age, when sea levels were low and wide sandy flats were exposed (Ollier and Pain 1996; Short 2003). The high dunes of Queensland such as Fraser Island are the highest dunes in the world. Leptosols are also associated with beach ridges (Tanner 1995) that are formed as beaches with

broad curved shapes and lengths often of many tens of kilometers, as seen in this aerial photograph of a pocket beach in the Bahama Islands where the beach ridges mirror successive storm deposit build up (Fig. 2). Cheniers on the Yangtze Delta (China) are also tens of kilometers in length (Yan et al. 1989), up to 500 m wide, and similar to bight coast cheniers (Otvos and Price 1979) along the Louisiana-Texas coast. As wind blows sand from the beach to make ridges, these accumulations eventually become stabilized to support soil formation. Beach ridges often join together to make a chenier or beach ridge plain (cf. Fig. 2) where the ridges usually consist of coarser materials than the intervening swales. The more inland ridges are older than nearshore ones and composition of the ridges may be quite variable. A recent study by Rink and Forrest (2004) regarding the accretion history of beach ridges on Cape Canaveral and Merritt Island, FL, estimated ridges to be $4,000 \pm 150$ years old on the peninsula and about 43,000 years old on the more landward Merritt Island. Average ridge spacing was 109 ± 20 m, giving an average ridge accumulation rate of 80 ± 8 years per ridge on the cusped foreland. The ridge accumulation rate is related to storm frequency (tropical storms or hurricanes); soil formation proceeded on the ridges subsequent to deposition. On a coastal plain in southeastern Australia, for example, the inland beach ridges are quartzitic in composition and date back to the Miocene, whereas the nearshore sets are calcareous and formed throughout the Quaternary to the late Holocene (Cook et al. 1977). Many Tertiary marine beaches are now found high and dry in Western Australia, at places like Eneabba, Yoganup, and Minninup (Lissman and Oxenford 1975) that are now some distance inland from the present shore of the Indian Ocean. More recent beach ridge systems

are described for the inner Rottneest Shelf coast near Perth in southwestern Australia by Searle et al. (1988) where the main geomorphic components in the area are shore-parallel Pleistocene eolianite ridges and their associated intervening depressions, and the Holocene units in basins, slopes, banks-nearshore platforms, beaches, and beach-dune complexes.

Anaerobiosis may slow pedogenesis where there are persistent high water tables that prevent leaching of soil constituents, inhibit redox cycles, or preclude subsurface horizon development. Poorly drained floodplains and coastal marshes host these kinds of soils.

Cryosols

Cryo-hydromorphic soils occur in Arctic, subArctic, and boreal regions under cold continental, (sub)humid, or semi-arid climatic conditions. They support a characteristic vegetation cover of dominantly taiga, forest-tundra, or tundra with a ground cover of lichen moss. These soils have permanently frozen subsoil, often at a shallow depth of <1 m, and occupy enormous areas (1,800 million ha) typically on Arctic coastal plains (Table 1). Some show a significant accumulation of organ matter (dominantly weakly decomposed tissues of oligotrophic plants) at the surface, others are mainly mineral (or organo-mineral) in nature. They are saturated with water during the entire period of thawing, but lack features associated with reduction or redistribution of iron. The more mineral soils often show the peculiar phenomenon of thixotropy. Thixotropic properties are defined as the ability of relatively compact fine-textured soil materials to transform under

Coastal Soils, Fig. 2 Beach ridge plain near the southern tip of Eleuthera Island, Bahamas. The succession of calcareous beach ridges represents a developmental sequence of deposition, often associated with phases of storminess, where younger dunes and soils developed on them occur closer to the shore and older dunes and associated soils occur farther inland. Stages of soil development are usually referred to as chronosequences, where greater profile differentiation occurs on the older dunes. Minimal profile developed associated with weak phases of pedogenesis produce Leptosols (Lithosols), Arenosols, and Cambisols on the seawardmost ridges. Other types of calcimorphic soils occur inland in association with longer times for pedogenesis to precede.

pressure into an apparent liquid and unstable state when saturated with loosely bound water (quicksand-like property). When pressure weakens, the material gradually regains its initial compactness. Cryosols have been previously described in Russia as Peaty Frozen, Taiga Frozen, Gleyic Frozen, and Destructive Taiga Frozen soils and more recently as Homogeneous (or Peaty-Duff) and Thixotropic Cryozems. In Canada they are known as Organic and Turbic Cryosols. In *Soil Taxonomy* (Soil Survey Staff 1975, Soil Survey Staff 1992), they correspond with soils having a pergelic soil temperature regime.

Fluvisols

The central concept of this group relates to soil developed in fluvial (alluvial) sediments. Fluvisols were previously recognized by a variety of names including but not limited to swamp soils, Lithomorphie soils, Brown soils, Groundwater Gley soils, and Vaaggronden (“Vague soils,” Netherlands). Whatever the name, these soils are deposited in aqueous sedimentary environments viz. (1) inland fluvial and lacustrine environments, (2) marine environments, and (3) coastal saltings or brackish marsh environments, of which deltas are a special case (Dreissen and Dudal 1989). Fluvisols occupy significant areas on deltas and fans, coastal barriers, and tidal flats (350 million ha) (Table 1). On aggrading coastlines, combinations of sand or shingle spits and offshore bars allow dunes to accumulate, giving shelter to a nearshore zone where

silts and organic muds accumulate in low-energy or quiescent environments. Tidal inundation brings additional supplies of new suspended sediment that flocculates in the water column but which eventually settles to the bottom to help accretion of marsh soils. Aggradation of marsh surfaces takes place relatively slowly and is often associated with strictly zoned vegetation according to the length of time the marsh is inundated. Creeks give tidal waters access to the marsh at flood tide and drain the marsh at ebb tide. Deltaic systems develop where rivers debouching in the sea bring significant amounts of material, providing coastal conditions are satisfactory for sediment accumulation, as seen here in Fig. 3 along the Netherlands coast. In the intertropical regions, particularly, the conditions are such that reducing conditions may be developed in which the sulfates in the seawater are reduced to pyrites. Sediments containing pyrites may become parent materials for acid sulfate soils.

Fluvisols show clear sedimentary layering or stratification in a major part of the profile. Soil formation may have affected the upper part of the profile to produce dark-colored surface horizons that are high in organic matter and which form in comparatively little time (Fig. 4). Also, the material in the upper part of the profile below the surface horizon may have lost evidence of sedimentary layering due to weathering and have acquired the color and structure of stronger developed soils. These juvenile soils tend to show little evidence of weathering and soil formation below 25 cm depth, except possible gleying. Permanent or seasonal saturation with water, causing recurrent anaerobic conditions and low

Coastal Soils, Fig. 3 Organic-rich soil developed in fluvial-deltaic sediments flanking the IJsselmeer. These soils, reclaimed by diking and drainage, are susceptible to flooding and find use as pasture lands and reserves. Many soils developed in parent materials derived from marine

sediments become extremely acid when drained due to oxidation of sulfur compounds. The low pH values of acid sulfate soils preclude many uses.

Coastal Soils, Fig. 4 Core from a polder soil in The Netherlands. Depending on the nature of sediment grain-size distributions in the original marine sediments, soil texture can range from sand to clay. The flights making up this continuous core show minimal effects of pedogenesis due to the high groundwater table and reducing conditions. The upper part of the soil profile may show redoximorphic properties (e.g., mottles) due to fluctuating water tables and alternation of reducing and oxidizing conditions. The length of the hydroperiod in the upper part of the profile largely determines surface soil characteristics.

biological activity, tends to preserve the original stratified nature of the original deposits. Consequently, the more important linkages of Fluvisols are with other weakly developed soils viz. Cambisols, Regosols, Arenosols, Leptosols, Gleysols, and Solonchaks.

Solonchaks

Solonchaks (from Russian *sol*, salt, and *chak*) are widespread in arid and semiarid regions, occurring widely (covering 260–340 million ha) in many parts of Asia, Australia, South and North America, China, and the Middle East (Table 1). Salts responsible for salinity have many origins in parent materials that are related to marine deposition; volcanic, hydrothermal, and eolian processes; and lithologic properties of initial materials. Mangrove deforestation contributes to

salinization of coastal soils, erosion, land subsidence, and release of carbon dioxide to the atmosphere. The presence of these salts, the amount of osmotic pressure of the soil solution, or the toxicity of a given ion leads to special landscapes, either occupied by salt-tolerant (halophyte) vegetation or characterized by the complete absence of vegetation (salt lakes, salt lagoons, salt pans, etc.), depending on the degree of salinity. Two chemical criteria are used to define these soils: (1) the solubility product of the accumulated salts or of salts that may form and (2) the ion concentration in the soil solution. To be considered salt-affected, the soils must contain an important quantity of salts that are more soluble than gypsum ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$: $\log K_s$ is -4.85 at 25°C), thus also more soluble than calcium carbonate, jarosite, and iron sulfide. For this reason, gypsiferous soils, calcareous soils, and soils with jarosite are excluded from the Solonchaks and have a home in the Gypsisols, Calcisols, and Thionic Fluvisols, respectively (Spaargaren 1994). These soils must also have a total salt concentration of the soil extract, expressed as the electrical conductivity (EC) within a depth of 125 cm of the surface. This minimum value, measured in a saturated paste extract (or in a 1:1 extract for very sandy soils) must be: (1) $>15 \text{ dS m}^{-1}$ (or mS cm^{-1}) at 25°C , if the pH is less than 8.5 (neutral salts) or (2) more than 8 dS m^{-1} if the pH is more than 8.5 (for alkaline carbonate soils) or less than 3.5 (for acid sulfate soils other than Thionic Fluvisols).

Chloride soils are of marine origin but influenced by the potential acidity of the soils under mangrove. The pH is very acid to acid (3.5–5) in reaction, calcium is almost lacking and sulfates, entirely derived from seawater, are present in only very small quantities compared to chloride. Sodium is dominant in the soil solution ($\text{CL} \gg \text{SO}_4 > \text{HCO}_3$; $\text{Na} \gg \text{Ca}$). White salt deposits (NaCl , CaCl_2 , MgCl_2) may occur at the soil surface as crusts or efflorescence, which seasonally can turn into brown powdery surface layers. Examples are noteworthy in Gambia and in the Casamance region of Senegal.

Neutral chloride-sulfate soils are mostly of marine origin, but can be enriched by sedimentary gypsum deposited by rivers. When the pH is near neutral, sulfates and chlorides occur, and carbonates, sodium, calcium, and magnesium are in variable proportions and exceed bicarbonates present in variable quantities. Salt deposits are mostly NaCl , CaCl_2 , and MgCl_2 associated with gypsum in the profiles. These soils are widespread and examples can be found in the alluvial plains, chotts, and sebkhas of North Africa, the Mexican Lagunas or playas, along the Euphrates River in Syria and Iraq, and in salt flats elsewhere.

Acid sulfate soils of marine origin are formed in potentially acid environments of mangrove vegetation (mangals) where acidification is promoted by dry periods in some tropical regions. When the environment becomes extremely acid ($\text{pH} < 3.5$), the result is acidolysis of clay and liberation of aluminum, iron, and magnesium; there is little calcium and chloride in these systems. The lack of bases and very low pH

prevents the formation of jarosite. Examples occur in Gambia, the Casamance region of Senegal, and in Guinea Bissau. In reduced condition, these soils classify as Thionic Fluvisols as they have a sulfidic horizon; in oxidized and acidified states, these soils may classify as Salic Fluvisols if the EC is sufficiently high.

Carbonate soils include alkaline bicarbonate-sulfate soils and strongly alkaline carbonate soils. They form in aerobic environments with the production of sulfates from sulfides present in the original marine muds. The liberated acidity is neutralized by an excess of sodium and calcium carbonates in the biogeochemical system. Variations of these soils are found in the polders of Tchad, New Caledonia, the Balkan region, and Australia. The Solonchaks occupy the lower parts of landscapes where runoff, seepage, and shallow groundwater can accumulate; they are separated from most other soils by having a high salt content at or near the ground surface.

Podzols

The term *Podzol*, meaning “white earth” is derived from the Russian terms *pod* (beneath) and *zol* (ash). These soils are widely known as acid ashy-gray sands over dark sandy loams (Buol et al. 1980). These two contrasting albic and spodic horizons, with an abrupt boundary between them, make these soils among the most dramatic, eye-catching, and photogenic soils in the world (Fig. 5). The setting in which such a soil is produced requires the combination of soil-formation factors that yield necessary conditions where there is accumulation of iron, aluminum, and/or organic matter in a subsoil horizon. Podzols thus occupy large areas where there are sandy parent materials from the tropics to the boreal climatic zone (485 million ha, Table 1). Many kinds of vegetation, including, grasses, can yield certain organic compounds that enhance podzolization, but litter from a certain few species of plants in particular foster such accumulations viz. the hemlock tree (*Tsuga canadensis*) in forests of northern latitudes, the kauri tree (*Agathis australis*) of New Zealand, and heath (*Calluna vulgaris* and *Erica* sp.) in northern Europe. Podzols additionally occur under a wide variety of trees (e.g., *Picea*, *Pinus*, *Larix*, *Thuya*, *Populus*, *Quercus*, *Betula*) and understory plants in moist climatic zones that are cool (e.g., Humid Meso- and Microthermal climates). Humic Podzols (Cryohumods in *Soil Taxonomy*) occur as dominant soils in Canada, for example, in the Maritime Provinces (e.g., Cape Breton and Newfoundland), in the coastal forests of the British Columbia mainland, and on coastal islands (Clayton et al. 1977). Extensive areas of these soils occur on the humid subtropical coastal plain of the southeastern United States. Impressive are the 9 m thick Bh horizons in Spodosols on the North Carolina Coastal Plain (Buol et al. 1980). Ages of these soils are extremely variable, some Spodosols being able to

Coastal Soils, Fig. 5 Spodosol (Podzol) developed in siliceous, Pleistoceneage Pamlico Sands overlying a portion of the limestone Atlantic Coastal Ridge along the subtropical southeast coast of Florida. Here, prominent albic tongues (eluvial zone) extend at least 1.5 m into the organic- and iron-rich spodic horizon (illuvial zone). These coastal Spodosols are extremely photogenic due to the extreme biochemical differentiation within the profile, dramatic contrasts in soil color, abrupt wavy horizon boundaries, and thick profiles.

form relatively quickly. Burges and Drover (1953), for example, reported evidence that 200 years were required to leach calcite from beach sand in New South Wales, Australia, but 2,000 years to produce an iron-Podzol, and 3,000 years to produce an iron-humus Podzol with pH as low as 4.5. An iron-Podzol in coastal California has been estimated at about 1 million years (Jenny et al. 1969). On coastal dunes in cooler climates, Podzols may develop within a few centuries, but in warmer or less humid climates Podzols require several millennia or longer periods to form (Sevink 1991). Dune soils are easily leached because of their high permeability and low water-storage capacity. Although sometimes high in carbonates, the acid buffering capacity of the non-calcareous fraction (e.g., quartz) is generally very low. As a consequence,

acidification proceeds rapidly with concurrent changes in soil-forming processes and profile characteristics. Rates of leaching and acidification are high in climates with a large precipitation surplus and low decomposition rates (because of low temperatures). In arid climates, leaching will be strongly reduced and mobile components such as carbonates and gypsum may accumulate within the solum. Accumulations of secondary carbonates (e.g., caliche, kunkar) are frequently cited in studies of Holocene drier systems in drier coastal zones.

Podzolization is thus a bundle of processes that bring about translocation, under the influence of the hydrogen ion, organic matter, iron, and aluminum (and a small amount of phosphorus) from the upper part of the mineral solum to the lower part (Buol et al. 1980). Cheluviation, the dominant process of soil formation of Podzols, involves the combination of two processes: (1) weathering of primary minerals (especially phyllosilicates) by organic complexing acids and (2) translocation of organic matter both in the weathering of primary minerals and in the translocation of Al and Fe complexes. These processes lead to special morphological and analytical characteristics that are used to identify a soil material as Podzolic. Cheluviation affects large areas of soils in the boreal zone. The process is also active in humid regions, especially in the temperate zone but also in the equatorial realm where many examples of Podzols have been described.

Podzols are soils characterized by the presence of an illuvial spodic horizon. In this horizon, amorphous compounds have accumulated consisting of organic matter and aluminum, with or without iron or other cations. The process of translocation and accumulation, known as cheluviation, is usually shown by the occurrence of an albic (bleached) horizon underlain by a spodic horizon. The illuviation of organic compounds can often be demonstrated by the presence of thick cracked organic coatings on the skeleton grains within the spodic horizon. In coarse sandy materials, Podzol morphology is well expressed and strong contrasts occur between eluvial (albic) and illuvial (spodic) horizons (cf. Fig. 5). In most Podzols, where clay percentage is often less than 10%, coarse texture ranges from sand to sandy loam. Accordingly, water retention capacity is low, less than 50 mm and, although Podzols develop in humid climates, they often show moisture stress. Podzols are very acid soils, with a pH ranging from 3.5 to 4.5 in surface horizons; the pH may increase up to 5.5 in lower horizons. The cation exchange capacity (CEC) is mostly due to the organic compounds present and base saturation is always very low. Organic matter has a high C/N ratio especially in the surface horizons ($C/N = 25$ or more) and in the spodic ($C/N = 20$ or more), indicative of low biological activity and slow degradation of organic matter.

The limits of the Podzols are determined by the minimum expression of the spodic horizon and the minimal contrast between the eluvial and illuvial horizons. Soils showing

evidence of illuvial organo Al/Fe complexes but lacking sufficient amounts of it to qualify for Podzols, form intergrades with Cambisols, Arenosols, and Gleysols. Podzols and intergrades are typical of a soil mantle on sandy coastal plains with poor quartzitic materials affected by a shallow water table.

Sesquisols, Ferralsols, Alisols, Acrisols, Lixisols

Sesquisols are soils either containing at shallow depth a layer indurated by iron (petroplinthite), or at some depth mottled material that irreversibly hardens after repeated drying and wetting (plinthite). *Plinthite* is an Fe-rich, humus-poor mixture of clay with quartz and other diluents that occurs as redoximorphic concentrations in platy, polygonal, or reticulate patterns (Shaw et al. 1997). These kinds of soils occur mainly in the tropics but examples are common to old landscapes in (sub)tropical and temperate regions. Those with a shallow petroplinthite horizon are known as (high level) laterites, ironstone soils, or Sols ferrugineux tropicaux a cuirasse. They have widespread occurrence in western Africa, especially in the Sudano-Sahelian region where they cap structural tablelands; they are also common in central-southern India, the upper Mekong catchment, northern Australia, and the eastern part of the Amazon region (Table 1).

The Sesquisols with plinthite are known as Plinthosols, groundwater laterite, sols gris lateritiques, or Plinthaquox (Soil Survey Staff 1992). They are found in extensively flat terrains with poor internal drainage, such as the late Pleistocene or early Holocene sedimentary basins of eastern and central Amazonia and the central Congo basin, but also on coastal plains such as in southwestern Western Australia (e.g., Swan Coastal Plain, Ridge Hill Shelf, Donnybrook Sunkland). Well-drained soils with loose ironstone concretions (sesquiskeletal material) are frequent nearly everywhere in the tropics and subtropics, in many landscape situations. The material is the result of former plinthite formation, subsequent hardening, and transport or re-weathering.

The central concept of Sesquisols is one of a soil affected, at present or in the past, by groundwater or stagnating surface water in which iron has been segregated to such an extent that a mottled (redoximorphic) layer has been formed which irreversibly hardens when exposed to air and sunshine. Included in the concept are those soils that have a hardened layer at shallow depth. The most important characteristic of Sesquisols therefore is the presence of plinthite and petroplinthite. Plinthite is an iron-rich, humus-poor mixture of kaolinitic clay with quartz and other diluents. It commonly occurs as red mottles in platy, polygonal, or reticulate patterns, and changes irreversibly on exposure to a hardpan or to irregular aggregates on exposure and repeated wetting and drying with free access of oxygen. In a perennial wet soil,

plinthite is usually firm but can be cut with a spade. A plinthic horizon is at least 15 cm thick in which plinthite takes up 10% or more by volume. Petroplinthite is a continuous layer of indurated material in which iron oxides are an important cement and in which organic matter is absent, or present only in traces. The Fe_2O_3 content is generally greater than 30%. The continuous ferruginous duricrust layer may be either massive, reticulate, interconnected platy, or columnar pattern that encloses non-indurated material. The indurated layer may be fractured, but then the average lateral distances between fractures is 10 cm or more and the fractures themselves do not occupy more than 20% by volume within the layer.

Sesquisols dominantly occur in intertropical regions and have linkages with Ferralsols, Alisols, Acrisols, and Lixisols. Sesquisols may occur in distinctly different landscape positions. Petric Sesquisols occupy the higher landscape positions, often as a result of landscape inversion due to lowering of the erosion base (McFarlane 1976). They now form tablelands and are usually freely drained. The other Sesquisols are found mainly in depressions or other areas with impeded drainage. On the Coastal Plain of Georgia (USA), for example, most soils have sandy surface horizons with high infiltration rates; many, however, have slowly permeable subsoil horizons with high concentrations of plinthite (Shaw et al. 1997) where only 10% platy plinthite is necessary to perch water (Daniels et al. 1978). These soils have developed from Miocene aged sediments and are classified in *Soil Taxonomy* in fine-loamy, siliceous, thermic families of Plinthaquic, Aquic, Arenic Plinthic, Plinthic, and Typic Kandiodults. In Georgia, more than 1.5 million ha of soils containing plinthite have been mapped. Sesquisols are found in association with Gleysols and Stagnosols in areas conditioned by hydromorphy, and with Ferralsols, Alisols, Acrisols, and Lixisols, which occupy the better-drained positions in the landscape.

Tropical weathering and pedogenesis produces Ferralsols that are characterized by a colloidal fraction dominated by low-activity clays (1:1 alumino-silicate minerals) and sesquioxides. These highly weathered soils lack rock fragments with weatherable minerals and are characterized by the presence of low-activity clays and a uniform morphology that lacks distinct horizonation. If there is sufficient iron in the original material, these soils are reddish in color and contain a weak pedal structure; there are few marks of other soil-forming processes such as clay accumulation through translocation. Secondary accumulation of stable minerals such as gibbsite or iron oxyhydrates may be present in concretionary forms (e.g., pisolites) as part of the fine earth fraction. Typical soils are situated on old geomorphic surfaces, which formed through erosion and deposition, and occur today as relict landscapes over large areas (750 million ha, Table 1). Having formed in transported and reworked colluvial materials, these

strongly weathered soils have little relationship with underlying geological strata. As a result of transport and deposition, the soils may be stratified (e.g., McFarlane 1976; Finkl 1980, 1984). In extreme stages of weathering in a free leaching environment, there is relative accumulation of sesquioxides and small amounts of 1:1 alumino-silicate minerals (e.g., kaolinite) as well as resistant minerals such as anatase and rutile. The sesquioxide minerals include goethite, hematite, and gibbsite; the alumino-silicate minerals are generally degraded kaolinites and some muscovite. In this weathering environment, neogenesis of alumino-silicates is rare with the possible exception of aluminum chlorite.

Occurring on geomorphically old surfaces, these soils are associated with Cambisols in areas with rock outcrops or where rock comes near to the surface. On the stable surface they occur together with Acrisols, which seem often to be related to the presence of more acidic parent materials (e.g., gneiss). On more basic rocks they occur associated with Nitisols, with no apparent relation to underlying rocks or topographic positions. Near valleys, Ferralsols merge into Gleysols.

Alisols (from *L. alumen*, alum), occurring in humid (sub) tropical and warm temperate regions, are acid soils with a dense layer of illuviated clay in the subsoil; they cover more than 100 million ha worldwide (Table 1). The intense weathering processes in these soils degrade 2:2 and 2:1 clay minerals and release large amounts of aluminum to create a very acid environment. Alisols correlate partly with Aquults, Humults, and Udults in *Soil Taxonomy* (Soil Survey Staff 1975, 1992), the Ferralsols or sols ferralsitiques tres lessive in French systems (e.g., AFES 1992; CPCS 1967), and Red Yellow Podzolic soils with a high clay activity in the Brazilian soil classification.

Acrisols (from *L. acris*, very acid) are characterized by a subsurface accumulation of active clays, a distinct clay increase with depth, and a base saturation (by 1 M NH_4OAc) of less than 50%. The soils have been named Red-Yellow Podzolic soils, Podzólicos vermelho-amarelo distróficos a argila de atividade baixa, sols ferrallitiques fortement ou moyennement désaturés (CPCS 1967), Red-Yellow Earths, Latosols, and oxic subgroups of Alfisols and Ultisols. The later have been redefined as kand- and kanhapl- great groups in *Soil Taxonomy* (Soil Survey Staff 1975, 1992). These soils are common in tropical, subtropical, and warm climatic regions, on Pleistocene and older surfaces that take up more than 900 million ha worldwide (Table 1).

The dominant characteristic of Luvisols (from *L. luere*, to wash) is textural differentiation in the profile that forms a surface horizon depleted in clay and an accumulation of clay in the subsurface argic horizon. These soils are further characterized by moderate to high activity clays and low aluminum saturation. These soils are known as sols lessivés in France, Parabraunerde in Germany, pseudo-Podzolic soils

in Russia, Gray-Brown Podzolic soils in earlier US terminology or as Alfisols in *Soil Taxonomy*.

Lixisols (from L. *lix*, lye) are characterized by a subsurface accumulation of low-activity clays (cation exchange capacity is less than 24 cmol(+)/kg) and moderate to high base saturation. They show a distinct increase in clay content with depth. These soils have been named Red-Yellow Podzolic soils, Podzólicos vermelho-amarelo eutróficos a argila de atividade baixa, sols ferrugineux tropicaux lessives, and sols ferrallitiques faiblement désaturés appauvris (CPCS 1967), Red and Yellow Earths, Latosols, and oxic subgroups in *Soil Taxonomy* (Soil Survey Staff 1992). Limits and linkages of Lixisols, Acrisols, Alisols, and Luvisols are entirely based on analytical properties. Therefore, in areas where these kinds of soils have CECs close to this value, they will merge into each other.

These soils, which are relict (out of pedogenic phase with the present environment) and not related to contemporary soil-forming processes in coastal zones, are nevertheless important pedogenic and geomorphic features along many coasts; they occur about 435 million ha worldwide (Table 1). Although commonly associated with truncated landsurfaces that produce coastal cliffs such as those seen on marine sediments along the eastern boundary of the Guiana Shield in northeastern South America (Valeton 1981); the coastal Trivandrum district in southern Kerala (India) (Karunakaran and Sinha Roy 1981); Long Reef Beach near Sydney, New South Wales (Retallack 1990); Darwin, Northern Territory (Australia) (McNally et al. 2000); and as lateritic spurs and benches along the Darling Fault Scarp in southwestern Australia (e.g., McArthur and Bettenay 1960), these weathering profiles also occur as reefs on seaward sloping surfaces that extend below present MSL (Short 2003) in the Northern Territory and into the Gulf of Carpentaria (Hays 1967). Interestingly, these Tertiary and older weathering profiles extend from northern Australia to the southern boundary of Papua New Guinea but are now drowned by the eastern Arafura Sea and Torres Strait. Depending on the thickness of the weathering profile and its intersection with present MSL, a variety of materials may occur along the shore with beaches or marine terraces developed in saprolite, pallid zones, mottled materials, or ferruginous duricrust.

In the case of the Darwin porcellanite (Darwin Member of the Bathurst Island Formation), a siliceous duricrust that was produced by leaching and replacement of preexisting rocks, the degree of alteration is less than that found in silcrete (McNally et al. 2000). Pisolithic ferricrete (lateritic or iron-stone “pea gravel”) occurs in close association with the porcellanitic duricrust throughout the Darwin area. A karstlike relationship between the two types of duricrust (porcellanite versus ferricrete) is exposed along road cuts in Darwin, as described by McFarlane et al. (1995) where the ferricrete fills cavities in the porcellanite. This ferricrete is pedogenetically unrelated to the old lateritic pallid zone that

developed in the Cretaceous sulfide-bearing marine muds following the retreat of the early Cretaceous sea. Porcellanization around Darwin is mostly confined to lower Cretaceous rocks that weathered to form the pallid zone of a laterite profile 50–70 million years ago. This deep weathering profile was later silicified in a number of cycles that were most intense during the Miocene (Milnes and Thierry 1992). Both silicification and ferruginization continue to the present day, as evidenced by cliff-base 1940s junk that has been cemented together in a kind of “bottlecrete” by iron-charged spring waters. Silicified and ferruginous “beachrock” occurs at Fanny Bay (Darwin) between the present high and low tide lines. McNally et al. (2000) report that these beachrocks occur in a groundwater discharge zone, indicating that some duricrusts have developed since the postglacial sea-level stabilization around 6,000 BP. Marine erosion along the Darwin coast cut marine benches and eroded cliffs into deep mantles of chemical weathering that retain lateritic and siliceous Paleosols. Slumps of pallid zone materials at the cliff base provide residual lithogenic quartz and secondary (epidiagenetic) agglomerated porcellanized particles as beach materials. Parts of the beachface are silicified and ferruginized to form an unusual kind of “beachrock.” Younger coastal soils have developed in the older deep weathering profiles that are exposed along the shore. Complicated polygenetic laterite profiles are also reported from Hong Kong (e.g., Wang 2003) where pedogenic and ground-water origins represent paleosurfaces that require prolonged subaerial exposure, quiescent tectonism, and a certain level of climatic stability.

Planosols

Planosols (from L. *planus*, flat) have a bleached, light-colored eluvial horizon that abruptly passes into dense subsoil with significantly higher clay content. These soils typically occur in seasonally or periodically wet, level areas, often above normal flood levels of nearby rivers or estuaries. Planosols occur on nearly level river or marine terraces in Southeast Asia from Bangladesh to Vietnam, southern Brazil, southern and eastern Africa, and southern Australia. On a global scale, Planosols occupy about 130 million ha (Table 1). Melanization, the addition of dark-colored organic matter, is the process by which a dark surface horizon extends down into the profile. This bundle of specific processes includes: (1) extension of roots from grasses in the profile, (2) partial decay of organic materials in the solum, (3) reworking of the soil and organic matter (bioturbation) by earthworms, ants, rodents, with the development of krotovinas (follod burrows), (4) eluviation and illuviation of organic colloids along with some mineral colloids, and (5) formation of resistant “ligno-protein” residues that give a dark color to these soils (Buol et al. 1980).

Cambisols

Cambisols (from *L. cambiare*, to change) are moderately developed soils that are characterized by slight to moderate weathering of parent materials. They do not contain appreciable amounts of illuviated clay, organic matter, aluminum and/or iron compounds. These soils are particularly common in temperate and boreal regions that were influenced by ice during recent glacial periods. The poorly developed profiles result because soil parent materials are young and because soil formation is slow under low temperatures (or even permafrost) of high latitudes in northern Russia and Canada. Cambisols also develop in pre-weathered, old parent materials where they occur in association with highly developed soils such as Acrisols and Ferralsols. The largest continuous surface of Cambisols in warm regions is found on young alluvial plains, terraces, and deltas of the Ganges-Brahmaputra river system. Cambisols are also quite common in arid climates, where they are closely associated with Calcisols. Cambisols cover an enormous area of about 1.5 billion ha worldwide (Table 1) and constitute the third largest major soil grouping in the FAO Revised Legend (FAO 1991). The minimum degree of soil development present in Cambisols separates them from Regosols. Leptosols are not permitted to have a cambic horizon and the shallowness of Leptosols separates them from Cambisols. When the cambic horizon reaches its maximum expression, Cambisols border soils defined by an argic horizon (e.g., Luvisols, Alisols,

Acrisols, Lixisols, Nitisols), a spodic horizon (Podzols), or ferralic horizon (Ferralsols). Definition of these horizons is such that the cambic characteristics are excluded.

Arenosols

Arenosols (from *L. arena*, sand) are sandy soils with slight to moderate profile development. These soils are widely distributed and form one of the more extensive major soil groups in the world. FAO (1991) estimates Arenosols to cover about 900 million ha (Table 1), or 7% of the land surfaces; if shifting sand and active dunes are included, the coverage is about 10%. Sandy coastal plains and coastal dune areas are, of course, of smaller extent but ecologically very important. Although Arenosols occur predominantly in arid and semi-arid regions, they are typical azonal soils that occur in the widest possible range of climates from very arid to very humid and from hot to cold. Arenosols occur predominantly on eolian sands, either dunes (Fig. 6) or flats, but have also formed on marine, littoral, and lacustrine sands of beach ridges, lagoons, deltas, lakes, etc. Other names for Arenosols include Psamments (Soil Survey Staff 1975, 1992), sols minéraux bruts (France), siliceous, earthy and calcareous sands, and various Podzolic soils (Australia), red and yellow sands (Brazil), and raw sands (Britain and Germany), among others. Arenosols thus have linkages with most other major soil groups. Only a few groups, such as Vertisols, have no

Coastal Soils, Fig. 6 Primary coastal dune on the Atlantic coast of southern Eleuthera Island, Bahamas. These Holocene carbonate dune sands are stabilized by vegetation and anchored to a rocky headland (photo center). Beachrock outcropping on the beachface helps to protect the dune foot from erosion.

Coastal Soils, Fig. 7 Exposure of fine-grained calcareous dune sands on the landward side of dunes. The imprint of pedogenesis is minimal and basically associated with accumulation of organic matter on the dune surface. Translocation of organic compounds down into the profile is limited to the upper half-meter or so.

linkages. The limits are determined by either textural requirements or the occurrence of certain diagnostic horizons within specified depths. Of most importance in their development are factors that limit soil horizon development in wetlands, alluvial lands, sand lands (Fig. 7), rocky areas, and various unconsolidated materials. The spatial distribution of Arenosols indicates that many factors are involved, which operate in various combinations to limit profile development: (1) dry but hot to warm to cold climates and microclimates that parse the amount and duration of water movement in the soils (Arctic, subArctic, Antarctic, and temperate and inter-tropical desert zones provide these conditions), (2) mass wasting and solifluction remove surficial material faster than most pedogenic horizons can form, (3) cumulization adds new material to the surface of the soil faster than new material can be assimilated into a pedogenic horizon, (4) immobilization of the soil plasma in inert materials, in carbonate-rich flocculated materials, and in some highly siliceous sediments to inhibit profile differentiation by illuviation, (5) exceptional

resistance to weathering (pedologic inertia) of some initial materials, (6) infertility and toxicity of some initial materials to plant growth that inhibits biogenetic differentiation (e.g., on serpentine barrens), (7) saturation with water or even submergence for long periods, (8) short exposure of initial material to active factors of soil formation (e.g., marine flats newly exposed by uplift), and (9) a recent drastic change in the biotic factor that initiates formation of a new pedogenic regime in an old one, which in turn serves as initial material (Buol et al. 1980).

Regosols

Regosols (from Gr. *rhegos*, blanket) are well-drained, medium-textured, deep mineral soils that are derived from unconsolidated materials and which have been traditionally separated from shallow soils (Lithosols, Leptosols, etc.) and from those of sandy or coarser texture (e.g., Arenosols). A Regosol does not have assemblages of diagnostic horizons, properties, or materials that are definitive for any other group of soils. Most properties of Regosols are associated with the materials themselves and not with genetically developed soil features. Conceptually, Regosols are the initial state for pedogenesis representing recently deposited or recently exposed, earthy materials on a ground surface; these weakly developed soils contain poorly defined horizons. Some soil materials, which represent a late stage of weathering with few distinguishing characteristics, are recognized as Regosols. For example, thin ferrallitic materials that cannot go into Cambisols and may be classified with Regosols (Spaargaren 1994). Although there are examples of initial stages of soil development in all landscapes throughout the world, the areal extent of Regosols is often limited and these soils are often inclusions in other soil units. Although of generally limited extent on a global scale (Table 1), Regosols can be important soils in specialized environments (e.g., tundra), such as Arctic plains in northern Canada where Cryic Regosols account for about 23.5% of Canada's land area (Clayton et al. 1977), extending from Labrador and Baffin Island on the east to the Mackenzie Delta in the west. Nearly 3,000 km² of Cumulic Regosols (Dystric Fluvisols in *Soil Taxonomy*) occur in tidal marshes adjacent to the Bay of Fundy in the Maritime Provinces as well as on coastal floodplains adjacent to the Yukon and Mackenzie deltaic river systems. In the terrain, Regosols are mostly associated with degrading or eroding areas, while other soils occur on aggrading, depositional, or stable areas. As time passes and soil formation proceeds, Regosols may develop into many other soils depending on the most important soil forming factor(s). Sand dunes on the central Delmarva Peninsula of Maryland and Delaware, for example, contain weathering zones that are represented by Regosols (Entisols in *Soil Taxonomy*) with profiles that are only a meter

or two in thickness (Denny and Owens 1979). Basal horizons in the dunes constitute an ancient weathering profile, truncated at the top and overlain by a younger deposit of sand. These so-called two-cycle dunes thus contain an older basal dune that is Wisconsinan in age and the early episode of weathering may have been early Holocene, a comparatively warm Hypsithermal interval. The surface sand may be no more than a few hundred years old, the result of deforestation and cultivation in colonial times (Denny and Owens 1979). The Sharon Coastal Plain in Israel is predominantly comprised by sand dune fields and eolianite ridges. Cliffs along this plain contain three major sand accumulation periods between 65 and 50 ka, from 7 to 5 ka, and from 5 to 0.2 ka (Frechen et al. 2002), that in turn seem to correlate with periods of sapropel formation in the Mediterranean Sea and so with periods of strongly increased African monsoon activity. The uppermost eolianite (calcareous sandstone) seems to correlate with a sapropel formed at about 7.8 ± 4.0 ka BP. Major phases of soil formation occurred between 35 and 25 ka resulting in a Rhodoxeralf soil (Grumusolic Dark Brown soil) and between 15 and 12 ka forming a Rhodoxeralf (hamra) soil. Frechen et al. (2002) identify at least seven weak pedogenic phases resulting in weakly developed horizons of Regosol-type soils that are intercalated in the eolianite sequences. The oldest eolianite layer contains kurkur (caliche) and seems to be about 55 ka bp in age.

Coastal Plain Soils

As a general rule, soils of younger landscapes are less differentiated (i.e., they contain simple sequences of horizonation and plasmic soil materials are unorganized) than those of older surfaces where weathering profiles tend to contain highly organized soil materials with complex horizonation (e.g., Butler 1959; Huggett 1975; Buol et al. 1980; Gerrard 1981; Ollier and Pain 1996). Because considerable time is needed to form differentiated soils where soil horizons and materials are highly organized, it is possible to sequentially arrange soils in chronological order with soils developed in young deposits placed before those formed later. Soils arranged in this way represent a sequence of development, referred to as a *chronosequence* (Jenny 1941). If prior conditions of weathering continue, the young soils in time develop characteristics seen in the oldest (Gerrard 1981; Ward and McArthur 1983). This is a simplistic interpretation of uniform and uninterrupted development, but other more complicated (interrupted) sequences are possible, such as apparent trends due to secular changes in climate, drainage, or biota. Investigation of elemental mass balance trends, based on element translocation patterns in response to climate forcing, show promise for estimating the weathering flux under drier or wetter mean annual precipitation regimes (e.g., Stiles et al.

2003). Optical dating of young coastal dunes (e.g., Ballarini et al. 2003) provides a tool for reconstructing coastal evolution on a timescale of decades to a few hundred years. Quartz optically stimulated luminescence (OSL) dating is based on the fact that OSL dates of less than 10 years are very well zeroed prior to deposition and burial, as demonstrated by Ballarini et al. (2003) for an accretionary coastal segment near Texel, The Netherlands. Other luminescence sediment dating methods, more amenable to timescales of a very few thousand years, have found application in the study of the activation and stabilization of coastal dunes on a North Carolina barrier island (Berger et al. 2003). Here, the quartz SAR (single-aliquot regenerative-dose method) is preferred for photonic dating in this region because of the relative abundance of quartz. These kinds of dating methods provide tight controls for estimates of pedogenic phases and the estimation of time intervals required to produce specific horizonation sequences in coastal dunes.

Radiocarbon dating is limited by the availability of datable materials and the technique can be applied only to younger soils (<50,000 year BP) that range from latest Pleistocene to Holocene in age (e.g., Vogel 1980; Bowman 1990). The prospect of dating and correlating coastal and bottom deposits as well as terrestrial-marine weathering sequences, as seen in coastal soils, is best achieved along the littoral where sedimentation and subsequent soil development are closely associated with changes in sea level (e.g., Karpytchev 1993). Lake-level histories as well can sometimes be gleaned from radiocarbon dates for coastal dune fields, as demonstrated by Arbogast and Loope (1999) for Holocene coastal dunes on the shores of Lake Michigan. When marine deposits are correlated with terrestrial weathering sequences by stratigraphic linkage at the coast, pedogenesis can be related to sea-level change and erosion-deposition cycles (Kukla 1977). If dates related to sea-level changes can be assigned to coastal landforms, then the chronology can be extended inland by using local markers (Ward and McArthur 1983). At the coast, abundant shells can supplement wood and peat as a basis for radiocarbon dating (Mook and van de Plassche 1986).

If there is uncrystallized coral present, then dates back to 200,000 years can be obtained from uranium decay methods, and on volcanic shores potassium/argon dating provides useful information. For coasts where these methods are not applicable, the principal means of dating refers to the correlation of stranded shorelines. If the former shores in one locality cannot be dated directly, it is sometimes possible to relate them to the shores in other localities where dates exist, assuming that changes in sea level are instantaneous and global (Ward and McArthur 1983).

Because the earth's crust is in dynamic equilibrium with the asthenosphere and tectonic adjustments are always taking place, no coastal landmass can be regarded as completely stable, no matter how free it is from seismic activity or

neotectonism. Few coasts are so mobile, however, that they contain no part of the eustatic record. Landforms in the coastal zone are complex and not all are only the product of terrestrial processes or marine action.

The apparent simplicity of most coastal plains is suggested by their lack of relief, which disguises these plains from their true nature as terminal geomorphic surfaces of complex transgressive-regressive depositional units laid down during glacioeustatic fluctuations. Bounded at the surface by terrestrial and marine erosional, transportational, and depositional landforms, the stratigraphic units (including paleosols) are limited below by unconformities of terrestrial and marine origin. Sedimentary facies between these surfaces reflect coastal plain (alluvial, palustrine, and eolian), estuarine, and marine open-shelf environments (e.g., Curray 1978; Davis 1978). Their evaluation requires a complete stratigraphic examination, as offered by Haq (1995) in summaries of the principles and concepts of sequence stratigraphy (the study of rock relationships within a chronostratigraphic framework wherein the succession of rocks is cyclic and is composed of genetically related stratal units viz. sequences and systems tracts).

Ideally, two main sedimentary sequences occur within a transgressive-regressive unit (e.g., Blum et al. 2001). The terrestrial sequence, which develops as sea level regresses seaward through lowering, results from extension of alluvial erosion and sedimentation, and of soil formation, into the coastal zone. The marine sequence forms during subsequent landward transgressions or rise of sea level when marsh, estuarine, beach, dune, and deltaic sediments are introduced. The relative thickness, significance, and spatial extent of these sequences depend on the dynamics of coastal processes and on sediment volumes brought to the shore by rivers. When major rivers deposit large volumes of alluvium at the shore, the marine contribution to the sedimentary pile is limited. Coastal landforms thus result predominantly from alluvial distribution.

Coastal strand plains with no alluvial contribution, such as those forming in the Holocene landscape of Gippsland, Victoria, in Australia (Ward 1977), lie at the other extreme of the scale. Relative placement of terrestrial and marine sediments here is determined by gradients at the coast, and by the history of eustatic fluctuations relative to the land. If, for example, sea level rises above a previous high stand, the earlier deposits will be truncated, buried, or partially submerged. Conversely, a eustatic fall will leave the earlier deposits stranded as a terrace.

Almost all the soils on the Swan Coastal Plain, southwestern Australia, are formed by material deposited by rivers (fluvial, alluvial soils) and wind (eolian soils). The Yilgarn Block (part of the West Australian craton), east of the Darling Scarp bordering the Swan Coastal Plain, was epeirogenically uplifted as part of cymatogenic movement and warping about 40–50 million years ago. This tectonic uplift increased the

differential between base level and the plateau surface causing erosion of the craton by rivers and streams. Detritus from deep chemical weathering (e.g., laterite profiles) or saprolite was either deposited onto the Swan Coastal Plain or carried to the sea (Fairbridge and Finkl 1980). The eroded material formed new parent materials for soil development on the Plain.

Broadly there are thus two major groups of soils on the Swan Coastal Plain. The first is a series of dune systems near the coast formed as a result of deposits from the sea, and including material originally derived from erosion of the Yilgarn block mixed with marine sediments. Once formed, the dunes can be eroded by strong winds. The sand is mostly eroded from the dunes nearest the coast, and is redeposited on the dunes further inland. The second major soil types are a series of soils formed by deposits directly eroded from the Yilgarn block and which comprise soils on an alluvial (Pinjarra) plain, occurring between the dunes and the scarp. There is a third, very narrow strip of soil, called the Ridge Hill Shelf, next to the scarp, formed from material eroded from the scarp.

Although different conditions prevail in different locations, some general principles emerge from regional comparisons. It is impossible to review the development of all coasts, but some cases illustrate the salient principles that are involved.

Soils of Coastal Dune Systems

Several distinct features characterize coastal sand dune systems (e.g., Cooper 1966; Nordstrom et al. 1990). The dunes themselves often show a regular succession from the more active and unstable foredunes at the back of the beach to older, more stable vegetated dunes inland (cf. Figs. 6 and 7). The other major element is the system of slacks or swales (low-lying, narrow coastal wetlands) that occur between the main dune or beach-ridge trends (cf. Fig. 2). Dune slacks are low-lying areas within dune systems that are seasonally flooded and where nutrient levels are low. They occur primarily on the larger dune systems in the United Kingdom, for example, especially in the west and north where the wetter climate favors their development when compared with the generally warmer and/or drier dune systems of continental Europe. The range of plant communities found in slacks is considerable and depends on the structure of the dune system, the successional stage of the dune slack, the chemical composition of the dune sand, and the prevailing climatic conditions. When a coastal dune forms, dune sand accumulates seaward if there is an abundant sediment supply or the dune grows to its maximum height and then moves landwards (Gerrard 1981). If the dunes are carbonaceous, leaching progresses with increasing age and when coupled with an increase in organic matter, there is a transition in soil reaction

from alkaline to acid conditions. The rate of leaching is initially rapid but declines as the amount of carbonate, rather than the amount of rainfall, becomes a limiting factor. The rate of leaching in the early stages also depends on the nature of the shell fragments and matrix grain size, being slower if the fragments are large. The process is temporarily halted if material is added to the dune system by wind action because leached and organic-rich layers are buried.

Differences in soil moisture between the younger and older dunes, and between dunes and swales direct soil formation in regard to oxidation of organic matter (Gerrard 1981). Young swales are initiated with a considerable advantage because nutrients and other minerals accumulate in the wetlands, a situation that is ultimately reflected in the soil profiles and pH values. The rate of increase of organic content depends on the initial lime content of the dunes. On lime-deficient dunes, early colonization by vegetation takes place with a concomitant increase in the rate of litter accumulation. As more acid conditions prevail, litter breakdown is inhibited and organic matter build up is promoted.

Swan Coastal Plain, Southwestern Australia

The tectonically stable limestone coastline of southwestern Australia is well suited to preservation signals of former sea levels. The eustatic record is limited by the time frame when lithified dunes formed in middle to late Pleistocene times. Fairbridge (1961) interpreted the field evidence in calcarenite sequences and Paleosols as fluctuation of sea-level against the

backdrop of a stable landmass, incorporating the curve in a proposed global standard. The sequence of former sea level stands was based on wave cut benches, submerged and stranded beach cobble deposits, karst, and marine bands associated with the Pleistocene limestone.

The Swan Coastal Plain in southwestern Western Australia presents a complex chronosequence of mid-Pleistocene to Holocene dune soils, the oldest interior sets (Bassendean dunes of siliceous sands with Podzol morphology) merging with a series of laterite-covered spurs of the Ridge Hill Shelf that form the foothills of the Darling Scarp (McArthur and Bettenay 1979). The Bassendean Dune System is the oldest of the dune systems of marine origin and today consists of a series of low hills varying from 20 m to almost flat, which rise to 110 m above sea level. They were formed as a belt of coastal dunes and associated shoreline deposits that accumulated mostly during a period of high sea level, about 115,000 years ago during the Riss-Würm interglacial period (McArthur and Bettenay 1979). Secondary or epidiagenetic calcrete commonly occurs in an interdunal area (between the Spearwood and Quindalup dunes), which is marine or estuarine in origin, as a cap on top of fossiliferous limestone that in turn is covered by a shallow sandy soil. The Swan Coastal Plain contains alluvium and dune sands (McArthur and Bettenay 1960). The fluvial deposits, displayed as coalesced alluvial fans, are of different ages and limited to the west by sequences of coastal dunes. The oldest Bassendean dune sequence is siliceous and Podzols have developed on them. The next Spearwood sequence has a core of eolianite beneath the weakly podzolized siliceous sand (Fig. 8).

Coastal Soils, Fig. 8 Exposure of the Spearwood Dune System on the Swan Coastal Plain, southwestern Western Australia, near Perth. This dune system was formed during the Würm I interstadial about 80,000 years ago. The surface soils are leached and the carbonate has been precipitated below to form layers and columns of hard, compact limestone deposited from solution by percolating waters. Infilled solution pipes are clearly evident in these calcareous dunes that show multiple phases of solution and precipitation, erosion and deposition, and soil formation. Many solution pipes contain a thin rind of travertine in addition to being infilled with Terra Rosa type soil materials.

The Quindalup dunes are calcareous and sequentially the youngest. Properties of the dune soils change in an orderly fashion with age. Assuming that the oldest was originally calcareous, there is progressive loss of carbonate, a lowering of the pH, and formation of Podzols. Between the two younger dune sequences is a zone that is marine in origin.

In the southern extension of the Swan Coastal Plain, the Quindalup dune systems extends along the coast and are backed by soils of the Stirling Swale, a marsh environment, and soils developed on older dunes farther inland (McArthur and Bettenay 1956). Alluvial and swamp soils occur still inland on the coastal plain. This sequence of dune systems, often calcareous near the coast and siliceous on the landward side of the coastal plain, separated by intervening swales is typical of many coastal plains around the world. Alluvial soils truncate these sequences as rivers make their way to the coast and swamps often prevail in older degraded dune systems.

Gippsland Area, Victoria, Australia

The coastal zone south of the Diving Range in Victoria is separated from the sea by a narrow sand barrier (Ward 1977). Generally characterized as extensive lowland with broad, low-lying sand plains and swamps around lagoons, 14 marine terraces elsewhere rise in shallow steps to the 130 m contour. Dune sands form low ridges on the marine terraces and alluvial terraces beside the main rivers terminate at former shorelines defined by stranded marine terraces, except for the youngest one that passes beneath present sea level. Three groups of soils are defined whether the parent sediment is eolian sand, alluvium, or stranded marine terraces. The soils on the eolian sands show progressive development of Spodosol characteristics when viewed in order of age. In the other groups, the most striking feature is the progressive development with increasing age of a contrast in texture between solum and subsoil. Changes in clay mineral suites and chemical composition accompany these changes in morphology.

Southeast South Australia, Australia

The most widespread soils of the Kingston-Mt. Gambier region in southeast South Australia are derived mainly from calcareous beach sands (Podzols and Terra Rossa profiles) or from estuarine and lacustrine deposits (Groundwater Rendzina and Solodized Solonetz profiles) (Blackburn et al. 1965). The calcareous beach sands occur in about 30 stranded Quaternary beach ridges that comprise a soil chronosequence with the oldest soils occurring more than 80 km inland from the present coast. Variation in morphological properties of the main kinds of soils shows gradual transition in age sequence

that is represented by depth of red soil, thickness of kunkar, and occurrence of ferruginous concretions (iron-rich pisolites). The time span for soil formation for some of the older soils appears to be on the order of several hundred thousand years (Blackburn et al. 1965). Most of the ridges are consolidated, immobile structures on which soil profiles show little evidence of truncation. In some places there is evidence of truncation in the form of secondary siliceous sand dunes and exposed kunkar. Most of the older landsurfaces are represented by non-truncated soil profiles of sand Podzolics.

Soils of Polar Coastal Plains

Cold soils occupy roughly one-third of the world's land area (Rieger 1983). Maritime and continental climatic types are recognized, but each has varying degrees of expression. In maritime types, precipitation is high and uniformly distributed throughout the year, and temperature differences between winter and summer are minimal. Many sediments and soils in Polar regions have a complex history, particularly as they relate to cyclic deposits, glacial activity, wind action, solifluction, as well as cryogenic processes (Tedrow 1977; Allard 2001). The coastal plain on the northern tip of Alaska is flat and the drainage pattern is poorly integrated. Barrow is a low-relief emergent region where lakes, marshes, or former lake basins occupy 50–75% of the region. The remainder of the coastal plain consists of initial surface residuals, areas that do not show evidence of thaw-lake activity. Black (1964) reports that the complexity of the surficial materials near Barrow makes it difficult to subdivide the geologic deposits. Beaches, bars, distributary deposits, and deltaic deposits are interspersed with shallow-water marine sediments and lagoonal, lacustrine, and fluvial deposits. The extremely low ground and air temperatures subdue chemical and biological activity that inhibits pedogenesis. Studying weathering in northeastern Greenland, Washburn (1969, 1973) defines the major weathering processes in terms of oxidation, formation of desert varnish, case hardening, rillenstein formation, carbonate coating, salt wedging, granular disintegration, differential weathering, exfoliation, cavernous weathering, frost cracking, and frost wedging. More recently, Rieger (1983) pointed out the morphological impacts of freeze-thaw cycles, hydrostatic mounding and fissuring, and cryoturbation (viz. turbation accompanied by icewedge formation), on soil formation in cold regions. Study of cryoturbated Paleosols associated with past ice-wedge activity on late-Holocene sandy fluvial terraces in northern Québec (e.g., Allard 2001), for example, corresponds with paleoclimatic information obtained from existing Arctic-wide and regional proxy records. The Little Ice Age stands out as a period of intense ice-wedge activity, followed by a warm thawing-out interval during the first half of the twentieth century. From AD 1946 to

1991, climatic cooling reactivated ice-wedge formation (Allard 2001). In some situations, especially in the main coastal tundra zone, some of the physical and chemical weathering processes are inseparable from incipient soil-forming processes (Tedrow 1977). Due to the adverse and specialized conditions in these cold lands, researchers recommend different kinds of soil classification systems, which are reviewed in Tedrow (1977). Modern soil classification systems tend to incorporate soil on cold coastal plains as part of more comprehensive approaches, rather than have separate systems for specialized soil environments. In the Canadian system (Clayton et al. 1977), for example, those cold region coastal soils that show weak profile development fall into the Podzolic (Humo-Ferric Podzol) great group. Mostly Spodic Cryopsamments (in *Soil Taxonomy*) and the Brunisolic order (Cambisols in FAO/UNESCO; Inceptisols, excluding Aquepts in *Soil Taxonomy*) provide for the more normal soils. The Regosolic order (equates to the concept of Entisol, excluding Aquepts, in *Soil Taxonomy*) provides for various soils with little or no profile development. Gleysolic orders (Aquepts, Aquepts, and some Fluvaquepts in *Soil Taxonomy*) include the gamut of poorly drained mineral soils with an organic layer up to 30 cm thick. Within the Canadian system, *cry* is attached to the names of 10 subgroups. The names Cryic Regosol and Cryic Gleysol indicate similarity to Regosol and Gleysol but also to those soils that are underlain by permafrost within a depth of 100 cm from the surface. The major genetic soils (excluding Ranker) of the tundra zone can be arranged in catenary form as described by Tedrow (1977) viz. Arctic Brown, Upland Tundra, Meadow Tundra, and Bog soil. The Arctic Brown represents zonal soils whereas the Tundra soil is indicative of hydromorphic conditions. Organic soils occur in low-lying, poorly drained coastal areas referred to as bogs, swamps, marshes, or muskegs. Since many coastal landscapes have been free of glacial ice within the Holocene (past 10,000 years) there are many depressions in the landscape, water-impoundment areas, and flat plains with sluggish surface drainage. Recently deglaciated landscapes tend to exhibit poorly developed surface drainage patterns that result in water-saturated environments and the formation of Bog soils. Russian investigators commonly refer to the presence of organic deposits in sectors that have “sculpture-accumulative” relief (Tedrow 1977). Where coastlines are elevated, the organic deposits are usually intermixed with windblown sand. South of Barrow in the Meade River basin, surficial deposits have a sandy character with numerous blowouts, sand dunes, and vegetative mats that are buried by blowing sand. The coastal plain west of the Colville Delta contains geologic materials that incorporate a marine facies with dunes and loess. Because floodplains and sandbars are exposed to the wind action in summer, soils in the vicinity of coastal rivers and deltas contain admixtures of windblown sediments. The sand and silt is blown inland by onshore

winds and deposited along the banks. Soil properties are characteristic for a xeric, willow-vegetated dune system along the river but where the dunes merge with tundra inland, the terrain is poorly drained and wetland soils develop.

Interesting organic-rich soils of cold regions are the ornithogenic soils of coastal continental Antarctica (Casey Station, Wilkes Land) where penguin guano plays an important role in nutrient cycles in the ecosystem (Beyer et al. 1997). During the breeding season, seabirds bring huge amounts of organic matter from the sea to the land and this organic matter has accumulated to considerable thickness and consists of a friable layer of droppings, feathers, shells, bones, and dead penguins (Ugolini 1972; Tedrow 1977). On Signy Island (maritime Antarctica), 5% of the total snow-free surface is made up of ornithogenic soils from penguin guano. The chemical properties of the ornithogenic soils changes rapidly after the abandonment of the rookeries by the penguins, mainly because of CO_2^- evolution and N and P release in the sea (Tatur 1989). Other processes include the formation of oxalic acids in the first few centimeters and simultaneous concentration of recalcitrant soil compounds such as chitin, urates, and phosphate minerals. Leaching of iron and organic P fractions and the accumulation into the subsoil in maritime Antarctica produces a spodic Bh dark brownish (5 YR 3/1.5) horizon under a pale gray (10 YR 5/2) AE horizon, which are typical of Podzols in temperate regions (Beyer et al. 1997).

Coastal Barriers and Soils as Transitional Biophysical Systems

Barrier systems are widespread throughout coastal areas (Jelgersma et al. 1970; Leatherman 1979) and form the parent materials of soils. The barrier usually forms offshore, and a lagoon or backbarrier flat develops between the main barrier and the mainland; barrier-lagoon systems usually show transgressive, stationary, and regressive facies assemblages as seen along the coast of China (Li and Wang 1991) and elsewhere. Distinctive soil suites similar in age develop on the barrier and the backbarrier flats (Daniels and Hammer 1992). Some barriers form on the mainland, so only the soils seaward and those in the geomorphically equivalent estuaries or lagoons are the same age as the barrier. Goodwin (1987) describing coastal soil-landform relationships, reports that on the Coastal Plain of the Carolinas in the United States, soils on the landward Talbot Plain are older than the soils on the seaward Arapahoe Ridge or the Pamlico Plain. The Arapahoe Ridge and its association with the Talbot Plain is an example of why stratigraphic relations must be proven because the form alone often leads to incorrect conclusions.

Barrier systems may be wide, such as those in South Carolina, or very narrow as the Arapahoe Ridge in North

Carolina (Goodwin 1987) or the Atlantic Coastal Ridge in southeastern Florida (Finkl 1994). These systems may be very smooth, broad flats with little local relief, or irregular as in prograding beach ridge systems (e.g., Tanner 1995; Rink and Forrest 2004). Most barrier systems are a series of barrier and backbarrier flats where the seaward soils tend to develop on sandy parent materials.

Soils formed in the barrier sediments typically are 80–95% sand, with fine and medium sands dominating (Markewich et al. 1986). Spodic or humate horizons are common in the sandy barriers; in the Netherlands, peat and gyttia interfinger with older dune systems and on top of the Older Dunes there is a strongly developed Podzolic soil (Jelgersma et al. 1970). The Younger Dunes began to form in the twelfth century and are weakly podzolized. The spodic horizons may be very few centimeters thick beneath dryer sites, or 6 or 7 m thick beneath broad flats with deep-water movement. Most soils on the Arapahoe Ridge have spodic horizons, as do soils on the beach ridge complex. The soils on the beach ridge are complex sands. The A1 and spodic horizons on the ridge are often discontinuous and thin. The soils in the swales have thick organic rich A horizons and distinct spodic horizons. Soils and vegetation change abruptly in response to differing hydrological gradients across the ridge and swale sequence.

Soils on the backbarrier flats can have a wide range of textures. Many backbarrier systems are extensive, have a nearly level surface, and have finer textures than the adjacent barrier.

Coastal Paleosols

Paleosols are soils that formed on landscapes of the past (Yaalon 1971). They are identified on the basis of soil-forming processes, which produce the soil profile morphology, that no longer operate due to changes in climate (Fig. 9), local environmental conditions, or because of burial by younger (terrestrial or marine) sediments (cf. Fig. 9), lava, or inundation (drowning) by the sea. Ruhe (1965) recognized three main types of Paleosols: buried, exhumed, and relict. *Buried Paleosols* form at the landsurface but are subsequently covered by sediment or other materials, a process that separates and removes the soil from the contemporary soil-forming zone (Fig. 10). The depth of burial or integrity of the covering layer (e.g., lava) must suspend the soil-forming processes and yet be rapid-enough to prevent development of a Cumulic soil profile. Common examples occur in coastal dune fields, on overwashed barrier flats or spits, or on chenier plains where the rate of episodic shifting sands is slow-enough for soil formation to proceed and the new material

Coastal Soils, Fig. 9 Weakly developed phases of pedogenesis in the disturbed upper part of a glacial till associated with the Ronkonkoma Moraine on Long Island, New York, USA. Two phases of soil formation (layers A and B), separated by intervening unweathered reworked sediments, occur near the upper part of the moraine, which advanced about 21,000 years ago as part of the latest Wisconsin glaciation cycle. Soil layer (A) is a buried soil or paleosol. Soil layer (B) is a contemporary

surface soil. This most recent phase of soil formation is represented by an organic-rich accumulation at the surface and melanization of underlying materials. The translocation of organic compounds and oxidation of iron imparts a darker color to the subsoil. View is from Long Island Sound toward an erosional exposure that provides morainic sediments and weathered materials to the littoral system.

Coastal Soils, Fig. 10 Paleosol bands (arrows) within a calcarenite sequence on the Atlantic coast of northern Eleuthera Island, Bahamas. These weak phases of soil formation took place during stable phases with the Wisconsin glacial cycle. Reactivation of dune formation imitated additional cycles of deposition followed by stabilization and soil formation. The dark color of the soil bands is due to oxidative weathering of iron-rich minerals that accumulated in the profile by eolian accretion. Note that the seaward portion of the dunes and intercalated soils have been eroded, leaving soil layers and dune stratification projecting outward to where the dunes once stood.

to be incorporated into the soil profile. Epidiagenesis is common and resulting changes in original soil properties and horizons (formed prior to burial) must be considered in interpretation of Paleosol composition. *Exhumed Paleosols* occur at the land surface when a buried Paleosol is uncovered by erosion of the blanketing material. These soils may be out-of-phase with existing environmental conditions, as they occur at the time of reexposure. Exhumed Paleosols are commonly found in calcarenite sequences or active (including periodically reactivated) dune environments. *Relict Paleosols* formed on preexisting landscapes but were never buried all the while environmental conditions changed to a different regime, leaving behind weathering products that characterized prior landscape conditions. Common examples occur in a variety of landscapes, but those associated with ancient tropical and subtropical land surfaces are exemplars viz. *Sequisols*, *Ferralsols*, *Alisols*, *Acrisols*, *Luvisols*, and *Lixisols*.

A common example of buried coastal Paleosols occurs in horizontally bedded sequences, as in tropical southern Florida where there are five distinct marine units punctuated by episodes of subaerial weathering (Enos and Perkins 1977). Exposure to the atmosphere and chemical weathering of the exposed rock by dissolution resulted in the formation of discontinuous bands of dense caliche-type crusts (pedogenic calcrete as also reported in the Bahamas by Brown 1986), Paleosols, freshwater limestone, and laminated crusts (Enos and Perkins 1977; Beach 1982). Identification of subaerial exposure surfaces is an accepted means of identifying boundaries (unconformities) between different stratigraphic subdivisions of the Quaternary units. Interestingly, some of these weathering surfaces are radioactive and referred to as Secondary Depositional Crusts (SDC) (Krupa 1999). These SDCs are typically associated with increased natural gamma radiation immediately below subaerial exposure surfaces. These SDCs seem to be related to the paleo groundwater interface (Krupa 1999; Harvey et al. 2002), which was formed by residual downward percolation of rainfall through the vadose zone. The SDCs exhibit elemental abundances (e.g., Ca, Mg, Al, Sr, Fe, U, Th, and K) above the natural background level for the area.

The Bermuda record is a complex mosaic of carbonate eolianites, shoreline-marine limestones, calcarenite *protosols* ("accretionary Paleosols"), and Terra Rossa Paleosols (Vacher and Hearty 1989; Herwitz et al. 1996). Sayles (1931) was among the first to recognize that alternation of marine limestones, eolianites, and Paleosols in local sections provides a record of Pleistocene sea-level fluctuations. Bretz (1960), drawing diverse observations into a comprehensive history, established the correlation that eolian and marine limestones were deposited during Pleistocene interglacials when the shallow platform (−20 m) surrounding Bermuda was submerged and that Terra Rossa Paleosols formed during glacial-age platform emergences. Solutional depressions often formed in the eolianites subsequent to dune stabilization and weathering to produce solution holes or pipes. These depressions were sometimes infilled with fine-grained sediment (Fe-rich dust) that weathered to red soils or Terra Rossa (Herwitz and Muhs 1995) (cf. Fig. 8). The recurrent stratigraphic pattern, as reported by Vacher and Hearty (1989), features an erosional coastline marine deposit overlain by a regressive eolianite. Where the interglacial complex is entirely exposed above present sea level, high-stand erosional coastline deposits can be traced down-dip into laterally extensive beach deposits of a depositional coastline. The beach deposits thus grade upward and laterally into eolianite, which in turn extends landward over the marine deposit and oversteps the erosional coastline deposits.

Bahamian paleosols, by way of another example of buried and exhumed Paleosols (Figs. 11 and 12), are predominantly

Coastal Soils, Fig. 11 Buried paleosol in the supratidal zone on the northeastern Atlantic coast of Eleuthera Island, Bahamas. This buried Paleosol is now partially exposed along the landward margin of an abrasion platform, indicating active erosion of dune cover sands.

Coastal Soils, Fig. 12 Close-up shot giving details of the buried soil layer seen in panoramic view in Fig. 11. The abrupt stratigraphic boundaries above and below the soil layers (arrows mark boundaries) and contrasting nature of all three materials verifies the independence of the soil layer, now partially truncated leaving just the stump of a former profile. The hammer and Kubiena box (for collection of undisturbed, oriented samples) are for scale.

calcium carbonate and contain minor amounts of mineral-insoluble residue (quartz, plagioclase, and clay minerals) (Boardman et al. 1995). There are at least four megascopically distinct Paleosols: laminated crusts, homogeneous crusts, breccia/conglomerate, and homogeneous matrix. All four types of Bahamian Paleosols and all mineralogic varieties of paleosols are found on stratigraphically equivalent rock units (Boardman et al. 1995). The number and character of Paleosol-bound parasequences on New Providence Island (Nassau), Bahamas, suggest that at least

five interglacial cycles are distinguishable. Whole-rock amino acid racemization (AAR) ratios confirm the stratigraphic sequence and indicate that isotope Stages 1 through 11 are likely included among eight depositional packages (Hearty and Kindler 1997). The Bahamian stratigraphic and pedogenic sequences, not unlike other calcarenite environments elsewhere, are complicated by the intricate stacking of similar materials in complex geomorphological settings that respond to fluctuating climates and sea levels (e.g., Carew and Mylroie 1994).

Similar late Pleistocene- Holocene coastal dune sequences and buried soils are described for the southeast Queensland coast by Ward and Grimes (1987), who suggest that Holocene sea level soon after 3,900 radio-carbon years BP was lower than present.

In addition to calcareous precipitates, other kinds of indurated materials related to ferruginous crusts and intensely weatherized materials are also common on coastal plains. Delaney (1966), for example, describes interesting mixed and contra-genetic sequences of caliche and laterite (Fe-duricrust) on the Rio Grande do Sul of southeast Brazil and northern Uruguay. Here, Quaternary units consist of a perched blanket of sand (the Itapoã Formation), arkosic sands and gravels (Graxaim Formation), the Serra de Tapes Laterite (a soil- stratigraphic unit), and a marine quartzose sand (Chuí Formation). The relict Serra de Tapes Laterite is not forming today and must have formed during a climate with high temperature and moderately high precipitation, conditions that do not exist on the coastal plain today. Pleistocene caliche was formed in a climate almost opposite to that of the Serra de Tapes Laterite.

Similar kinds of relationships are found in cold regions where ice-permafrost sequences on the Siberian coastal plain, with large polygonal ice wedges, represent excellent archives for paleoenvironmental reconstruction. Such deposits contain numerous well-preserved records (ground ice, Paleosols, peat beds, fossils), which permit characterization of environmental conditions during a clearly defined period of the past 60 ka (Schirrmeister et al. 2002). Lake plains along the eastern shore of Lake Michigan provide analogous setups where buried soils occur in dune fields with cyclical development after relatively long (>100 year) periods of low sediment supply (Loope and Arbogast 2002). Because soil formation takes place during stable landscape conditions, the presence of buried soils facilitated construction of a general hypothesis for late Holocene interaction of foredune and perched dune models on this lake plain, as it relates to multicentury lake-level fluctuations. It seems, on the basis of this study of 32 dune fields and included Paleosols, that the modern landscape originated after the postglacial peak in lake level (i.e., after the Nipissing transgression, about 5,500–5,000 cal year BP) (Loope and Arbogast 2002).

The aforementioned descriptions feature Quaternary soils in contemporary coastal landscapes, but there are numerous other Paleosolic developments along ancient shores where old weathering sequences persist in the form of deep weathering profiles of the lateritic or bauxitic type in senile landscapes. Salients among these examples are found in the formation of lateritic bauxites in Cretaceous and Tertiary coastal plains. Bauxites commonly form elongate belts hundreds of kilometers long, parallel to lower Tertiary shorelines in India and South America (Valeton 1983). Typical sediment

associations are found in India, Africa, South and North America, that are characterized by: (1) red beds rich in detrital and dissolved material of reworked laterites, (2) lacustrine sediments and hypersaline precipitates, (3) lignites intercalated with marine clays, layers of siderite, pyrite, maracasite, and jarosite, and (4) marine chemical sediments rich in oolitic iron ores or glauconite. The geographic relationship between in situ lateritic bauxites and the shoreline at the time of bauxite formation are interesting, if not somewhat controversial. Occurrences of bauxites residing parallel to ancient coastlines is documented for the karst bauxites of the Mediterranean (Southern France, Greece, Yugoslavia). Most of these types of lateritic bauxites, which are soft at the time of formation, belong to the Aquox subgroup of the group of Oxisols in *Soil Taxonomy*. The Fe-rich parts eventually form hard ferricretes whereas the Al-rich parts form hard alucretes (Goudie 1973).

Alternating sequences of landscape stability and instability, as related to phases of soil formation in shield areas, are comprehended in the *cratonic regime* (Fairbridge and Finkl 1980). This model recognizes a thalassocratic-biostatic condition (a long-term stable phase) during which prolonged deep chemical weathering takes place. In contrast, the epeirocratic-rhexistatic condition is a shorter-term unstable phase when there is general ecological stress and erosion of weathering profiles. The dual-phased, long-term-short-term regime was developed from experience on the West Australian craton (Yilgarn Block) but is applicable to other cratonic margins around the world. The significance to coastal soils relates to occurrences of laterites, bauxites, and associated materials along contemporary coastlines and ancient shores. Phases of soil formation are related to landscape stability and high sea levels; erosional phases where there is stripping of weathered materials from the land surface is associated with low sea levels. This sequence of events along cratonic margins produces a wide range of distinctly contrasting coastal Paleosols that include and which are derived from residual weathering that juxtaposes Quaternary coastal plain soils with relict Tertiary and older weathering profiles.

Epeirocratic-rhexistatic phases on the Yilgarn Block (West Australian craton) have, for example, resulted in the stripping of regolith materials from the craton surface to produce a series of etchplains that represent degrees of soil removal (Finkl and Churchward 1973; Finkl 1979). The least amount of stripping is associated with incipient etchplains, which occur on the seaward-most margins of the craton, along the north-south trending Indian Ocean coastal boundary and along the east-west trending Southern Ocean coastal fringe. Buried etchplains occur on the southern margin of the craton where deep chemical weathering profiles are intersected by present sea level and overrun by coastal dune systems.

Conclusion

Coastal soils are, in a certain sense, almost enigmatic because most soils occurring in coastal zones have complex histories and are related to environmental conditions that no longer predominate. This fact is perhaps not surprising because coasts themselves are extremely complex, resulting from combinations of land movements and fluctuations of sea level. Some coasts thus have histories of ingression where relative sea-level rise drowns preexisting landscapes (Kelletat 1995). The accompanying soils become drowned or are buried by younger coastal sediments and new phases of soil formation. In other cases, the seabed becomes emergent by sea-level fall or neotectonic uplift providing new parent materials for soil formation. In other situations, the land-sea boundary remains more or less stable long enough for soils to develop in coastal deposits such as mangrove muds. Whatever the mechanisms involved, there exists a diverse range of soils in coastal zones. Some are clearly “coastal” in the sense that they are closely related to present shoreline materials and conditions; they are therefore younger Holocene in age. Other soils occurring in coastal zones are not strictly “coastal” because they can form independently of maritime conditions. The complex array of coastal zone soils is not easily comprehended without careful study and some background in pedological concepts, principles, practices, and field experience. Complex terminologies of different soil classification systems also tend to confound all but the most intent coastal researchers who make the effort to ferret out the details. Coastal soils are an interesting topic that offers scope for studying coastal change or evolution as recorded in the pedological record.

It is seen that coastal zones contain the youngest soils on earth as well as some of the oldest. Newly exposed seafloor muds form parent materials for acid sulfate soils and Solonchaks, recently stabilized coastal dunes host youngest Holocene Regosols whereas some older dunes feature strongly differentiated Pleistocene Podzols. Holocene Gleysols and Histosols form in juxtaposed swales and slacks where drainage is poor. Planosols and Solonetz occur on marine terraces and deltaic regions along with Histosols, whereas Cryosols and Leptosols characterize cold region coastal lowlands. Developed on older coastal plains in the low to middle humid latitudes there is a range of pedogenic formation that includes Podzols, Planosols, Aliosols, Luvisols, and Arenosols and Calcisols in drier realms. Deltaic plains often feature Fluvisols, Planosols, Solonetz, and Histosols. Ancient surfaces truncated by coastal erosion, especially in intertropical regions, show Sesquisols, Ferralsols, Alisols, Acrisols, and Lixisols. Last but not least there are Anthrosols that characterize pedogenic regimes in coastal areas where there has been a long record of human habitation and cultivation of field crops. This description of coastal soils may seem like a long

digression, but it is actually a light vignette because the situation is far more complex than what has been alluded to here.

This overview nevertheless provides a fair indication of the range and complexity of pedogenesis in coastal zones as well as indicating the close interrelationships between coastal processes, landforms, vegetation, hydrology, maritime climates, sediments, and the imprint of biochemical weathering on coastal landscapes and seascapes. More importantly, however, is the fact that coastal soils provide much biophysical information that is useful in attempts to unravel some of the major events in coastal evolution, especially phases of soil formation that correspond to sea-level stillstands and landscape stability.

Coastal Subsidence

Zhongyuan Chen¹ and John Rybczyk²

¹Department of Geography, East China Normal University, Shanghai, China

²Huxley College of the Environment, Western Washington University, Bellingham, WA, USA

Introduction and Terminology

Coastal subsidence, which can be described as the downward displacement of the land relative to sea level, often occurs in deltaic regions associated with riverine and estuarine sedimentation. These regions are commonly sites of thick deposits of Tertiary, Pleistocene, and

Holocene sediments, exceeding 12,000 m in the Mississippi River delta, for example (Penland et al. 1988). Coastal subsidence in these depositional zones are a function of five processes, each described in detail below: (1) downwarping, (2) tectonic activity, (3) consolidation of Tertiary, Pleistocene, and Holocene deposits, (4) shallow subsidence, and (5) underground water and gas extraction (Fig. 1). When only natural processes are considered, 1 + 2 + 3 define deep subsidence. Shallow and deep subsidence combined equal total subsidence (Cahoon et al. 1995).

Eustatic sea-level rise (the global sea-level rise due to changes in the volumes of glaciers and ice caps, and due to density-temperature relationships) can also be viewed as a “relative” land sinking or subsidence process. On a global scale, eustatic sea levels have risen approximately 125 m

Coastal Subsidence, Fig. 1 Processes contributing to total subsidence in coastal regions. Comments and numbers in parentheses indicate the relative magnitude of each process in the Mississippi River delta, a region where coastal subsidence has been intensely studied (modified and redrawn from Penland et al. 1988)

since the last glacial maximum 18,000 yr. BP. Current rates of eustatic sea-level rise are estimated at 0.15 cm yr^{-1} (Church et al. 2001). The term “relative sea-level rise” is used to describe deep subsidence plus eustatic sea-level rise because it is often difficult to differentiate deep subsidence rates from eustatic sea-level rise along the world’s coasts.

Downwarping

The weight of thick sediment sequences deposited during the Quaternary by major rivers that have discharged considerable sediment load, such as the Amazon, Yangtze, Mississippi, Yellow, and the Ganges/Brahmaputra has caused downwarping of the underlying crust (Fig. 2) (Coleman 1982; Chen et al. 2000). For example, in the Mississippi River delta, the combined weight of Cenozoic deposits accumulating in the geosyncline off the river mouth has resulted in the slow downwarping the Mesozoic basement. However, this process, estimated to be occurring at an average rate of

0.2 cm yr^{-1} , accounts for only a small fraction of total subsidence in the region (Penland et al. 1988).

Tectonic Activity

The tectonic-fault framework that exists in coastal regions can sometimes control the geomorphic configuration of the coast-delta extension (Coleman 1982; Chen and Stanley 1995) and the intensity of the fault motion plays an important role in influencing the overall subsidence rate (Stanley, 1988; Chen and Stanley 1995). On a large-scale, fault tilting can trigger the diversion of large rivers from one region of a coast to another. Consequently, the estuarine depocenter marked by the thickest sediment sequences, and the most active subsidence, switches laterally. The subsidence triggered by tectonism is a long-term and episodic, geologic processes that is difficult to distinguish from the subsidence caused by the long-term compaction of Cenozoic sediments. A regional estimate of tectonic subsidence along the coast can be made by evaluating subsurface data including petrologic, litho- and chronostratigraphic descriptions from a series of boreholes through sedimentary sections.

Consolidation of Tertiary, Pleistocene, and Holocene Deposits

The consolidation of Tertiary and Pleistocene marine and riverine deposits can be a significant component of total subsidence. However, it is the consolidation of Recent sediments that is considered the primary cause of background subsidence in coastal regions. Large amounts of riverine sediments deposited over the past 15,000 years have accumulated along coastal depocenters resulting in high rates of subsidence, regionally. This consolidation, or compaction, is caused by the dewatering of sediments (primary consolidation), the rearrangement of sediment structure (secondary consolidation), and the decomposition of organic matter. In some parts of the Mississippi River delta, subsidence rates due to consolidation exceeds 0.6 cm yr^{-1} (Penland et al. 1988).

Shallow Subsidence

The compaction in the upper 5–10 m of the sediment contributes a shallow component that is often overlooked when calculating total subsidence in coastal regions (Cahoon et al. 1995). Shallow subsidence is the result of primary consolidation and the decomposition of organic matter. It is an especially important process in coastal systems under stress (from flooding or salt, for example) where below ground plant structures, such as roots and rhizomes, die and decompose,

Coastal Subsidence,

Fig. 2 Diagram showing the gravitation subsidence both in the Mississippi and Yangtze estuarine depocenters. (A) The Mississippi model indicating the more seaward displacement than the downward, resulting in tremendous reverse mud slump in front of the river mouth region (modified after Coleman 1982), and (B) The Yangtze model indicating downward and seaward sediment displacement

leading to rapid subsurface collapse. In the Mississippi River delta, for example, high rates of relative sea-level rise in the coastal marshes have lead to increasingly long periods of flooding, plant mortality, and rates of shallow subsidence that exceed 2.5 cm yr^{-1} .

Underground Water and Gas Extraction

In some coastal regions, large amounts of fresh groundwater have been extracted along the coast for industrial, agricultural, and domestic use. Rates of subsidence due to this process can be alarmingly high, although the effects are usually localized. For example, subsidence rates within the Po delta of Italy and the Yangtze delta of China have, in the some past years, exceeded 30 cm yr^{-1} , due largely to groundwater withdrawal (Cencini 1998; Chen 1998). The reinjection of salt water into the substrata, to replace extracted fluids, has been successfully used to slow down or even halt, but not reverse, extraction-induced subsidence. Hydrocarbon extraction along the coast has the same potential for causing land subsidence, but has been less studied.

Methods of Measurement

Estimates of deep subsidence are usually based on long-term records from tide gauges that are mounted on stable piers, bridges, and pilings that extend through the shallow subsidence zone (and thus do not include shallow subsidence). A tidal gauge record spanning at least 18.6 years is required to factor out variations due to the moon's nodal cycle. Typically, mean annual or monthly water levels are regressed against time to yield a rate of relative sea-level rise (Emery and Aubrey 1991). To estimate the deep subsidence component of relative sea-level rise, the eustatic component (currently 0.15 cm yr^{-1}) is then subtracted. Eustatic sea-level rise is derived from the analysis of tide gauge data from coasts worldwide that are assumed to be geologically stable (Penland et al. 1988).

In addition, a radiocarbon-dated stratigraphy can help to calculate the net subsidence rate along the coast (Stanley 1988). Stratigraphic analysis of sediment borings can serve to define the subsurface configuration of Recent deposits. Isopachous maps of the Holocene sediment sections can also reveal thickened sediment sequences along the coast.

Moreover, high-resolution seismic profiles can provide evidence of Recent subsidence. Deformed late Quaternary strata, mud slumps, diapirs, tilted bedding, and gas-deformed structures in Holocene sequence imply remobilization of underconsolidated sediment within and adjacent to the estuarine depocenter (Chen et al. 2000). Deformation types and their specific position relative to the depocenter record the displacement of sediments as a result of compaction due to sediment overburden.

The tidal gauge technique for estimating subsidence (described above), and most estimates of subsidence reported in the literature, measure only deep subsidence, even though rates of shallow subsidence can greatly exceed the rates of either of these processes in some marshes (Cahoon et al. 1995). A recently developed field technique that uses a sediment marker horizon (such as feldspar clay) in conjunction with a surface elevation table (Fig. 3), an instrument that measures changes in elevation relative to a shallow subsurface datum, has made it possible to measure shallow subsidence (Cahoon et al. 1995).

Coastal Subsidence, Fig. 3 A surface elevation table (SET), shown in use with a feldspar marker horizon, used to estimate rates of shallow subsidence in coastal systems (Figure courtesy of Jim Lynch, and Don Cahoon, United States Geological Survey)

Subsidence and Its Implications

In stable or prograding coastal systems, relative sea-level rise is usually balanced by the accretion of fluvial or reworked marine sediments. However, extensive hydrologic alterations such as dams and levees have sharply reduced the amounts of fluvial sediments transported to coastal regions. As a result, saltwater intrusion, flooding, and coastal erosion has become much more prevalent in the past 100 years. In the Mississippi River delta plain, for example, land loss rates exceed $65 \text{ km}^2 \text{ yr}^{-1}$, due largely to a subsidence/accretion imbalance. To add to this problem, the eustatic sea-level rise component of relative sea-level rise is expected to accelerate over the next 100 years due to global warming (Church et al. 2001). Therefore, accurate measurements of coastal subsidence are vital for planning coastal protection in densely populated and low-lying region vulnerable to marine inundation.

Coastal Temperature Trends

George A. Maul
Department of Ocean Engineering and Sciences, Florida
Institute of Technology, Melbourne, FL, USA

Definition

Coastal water temperature trends – sea surface temperature values per unit time – are an indicator of global change.

Introduction

Few long-term records of coastal water temperatures are extant, but from many tide gauge sites of the U.S. Coast and Geodetic Survey (C&GS – now incorporated into the National Ocean Service of the National Oceanic and Atmospheric Administration, NOAA), there are handwritten observations covering much of the twentieth century. In the 1990s, NOAA switched to digital thermistor sea surface temperature measurements. Herein the digitized handwritten records are concatenated to the thermistor records, and century-scale SST trends are calculated.

Prior to the development of acoustic tide gauges and digital data-logging and transmission, trained tidal observers would visit C&GS primary tide gauge sites, typically on a daily basis. Their duties included comparisons between the marigram and the tide staff, measuring sea surface temperature and density and performing routine maintenance. The sea surface temperature (SST) values were recorded on standard forms, and mean monthly and annual values were calculated. These data forms were then archived and largely ignored. Only twenty or so C&GS tide gauge station temperature records of significant multidecadal length have been recovered and are analyzed in detail by Maul et al. (2001).

Tidal observers determined SST by lowering a bucket from the pier or other structure supporting the tide gauge, retrieving a sample of water, and measuring the temperature with a standard mercury-in-glass thermometer. Seawater density was also measured with a hydrometer (USC and GS

1929). In typical Coast and Geodetic Survey tradition, all instruments were numbered and routinely calibrated, with emphasis on data quality dating back to 1807 when President Thomas Jefferson founded the agency.

In the acoustic tide gauge, the thermistor is placed at the intake of the stilling well (vertical pipe that houses the acoustic hardware). Thus the temperature measured at high tide might be 10 m below the sea surface and at low tide 1 or 2 m below. If the water at the tide gauge site is vertically well-mixed, the SST and intake temperatures should be comparable. The thermistor data are archived every 6 min in concert with the water level measurement. Annual mean SSTs are calculated by averaging all 8760 hourly thermistor observations for a given year (8784 h in leap years). The thermistor data are available from NOAA at <https://tidesandcurrents.noaa.gov>.

Discussion

The longest record is from San Francisco, California. The historical C&GS SST data (1856–1994) are concatenated to the thermistor data (1995–2015) and are shown in Fig. 1. Typical of these data sets are gaps of various length. Some gaps are 1 or 2 years, others are decades long. The straight dotted line in Fig. 1 is the linear trend over the entire 1856–2015 record. Trends in annual mean SST are calculated by standard linear least-squares methods where an equation of the form $T = a \cdot t + b$ (where T is temperature, a is temperature trend ($\partial T / \partial t$) in °C per century, t is time in years, and b is the linear intercept) is fitted to the data.

Table 1 is the summary statistics of the longer SST records. The first column lists the sites, chosen to represent biogeographic regimes around the coastal United States with century-scale data. Columns 2, 3, and 4 are the years, number of years excluding gaps (N), and the trends $\pm$ the standard error of the trend of the historical C&GS data, respectively. Columns 5, 6, and 7 are the years, N , and trend statistics of the combined data. The thermistor data are only two decades long, a record far too short for trend analysis separately.

In general, concatenating the thermistor temperatures to the C&GS temperatures causes the trend to increase. Whether this is due to the change in measuring technology or coastal warming is uncertain. Lengthening the record on the other hand seems to decrease the uncertainty estimate of most trends. Baltimore, MD, and Galveston, TX, uncertainty both decrease from ± 0.5 °C per century to ± 0.3 °C per century. For the most part, the added thermistor data seems to blend well with the older thermometer data – there being no statistically significant difference in the mean temperatures in the 1980–2010 timeframe.

There is a nonsignificant degree of variation from locale to locale. The largest SST trend is at Baltimore, MD. This

Coastal Temperature Trends, Fig. 1 Time series plot of SST San Francisco, California. Note the missing data, which is typical of many such geophysical records, and the interannual variability

Coastal Temperature Trends, Table 1 Sea surface temperature (SST) trends from NOAA tide gauge sites

Station	Years	N	Trend ^a	decs	N	Trend ^a
Boston	1921–1994	73	0.5 ± 0.3	1921–2014	87	0.8 ± 0.3
Baltimore	1914–1993	65	0.9 ± 0.5	1914–2015	80	1.3 ± 0.3
Charleston	1922–1992	70	-0.1 ± 0.3	1922–2014	79	0.8 ± 0.3
Key West	1926–1994	36	0.0 ± 0.3	1926–2015	47	0.4 ± 0.2
Galveston	1922–1992	35	-0.9 ± 0.5	1922–2015	49	-0.2 ± 0.3
Los Angeles	1923–1991	40	0.8 ± 0.4	1924–2016	61	0.2 ± 0.4
San Francisco	1856–1994	79	0.4 ± 0.1	1856–2015	95	0.4 ± 0.1
Seattle	1923–1993	41	0.0 ± 0.4	1923–2015	61	0.0 ± 0.2
Seward	1926–1993	29	0.1 ± 0.4	1926–2013	44	0.8 ± 0.3

^a°C per century

unusually large trend, $a = 1.3 \pm 0.3$ °C/century, may be caused by the geography of Baltimore Harbor, by a general warming of Chesapeake Bay, and/or by urbanization of the marine environment. Nearby Boston ($a = 0.8 \pm 0.3$ °C/century) also shows significant warming as does Charleston, SC ($a = 0.8 \pm 0.3$ °C/century). Note however how the trend at Charleston has markedly changed after concatenating the thermistor data. The average Charleston temperature of the thermistor data (2001–2014) is 21.0 ± 0.6 °C, and the average of the juxtaposed 1980–1993 C&GS temperatures is 20.1 ± 0.5 °C. Although the difference between 21.0 ± 0.6 and 20.1 ± 0.5 is not statistically significant at the 95% confidence level, 2001–2014 is notably warmer. In the mid-1990s, the Atlantic Multidecadal Oscillation switched to a warm phase, which in part, may be the warming measured at these three tide gauges.

The Gulf of Mexico region, on the other hand, shows little statistically significant warming or cooling. At Key West, FL, the southeastern region’s most oceanic site, $a = 0.4 \pm 0.2$ °C/century, a slight warming trend. Galveston, TX, on the other hand, shows a small cooling trend of -0.2 ± 0.3 °C/century. As with Charleston, concatenating the thermistor data has markedly changed the trend at both Key West and at

Galveston. There is no evidence of acceleration in SST trend in these or any other station in this entry (i.e., fitting exponential or polynomial equations to these data does not explain additional variance r^2).

Along the US west coast, the SST trends among the sites are most similar: Los Angeles, CA ($a = 0.2 \pm 0.4$ °C/century); San Francisco, CA ($a = 0.4 \pm 0.1$ °C/century); and Seattle, WA ($a = 0.0 \pm 0.2$ °C/century). There is an important difference between Seattle, WA, and Seward, AK ($a = 0.8 \pm 0.3$ °C/century). Highly populated Seattle is well within Puget Sound with no large rivers to flush the estuary, and Seward (population 2,500) is at the head of Resurrection Bay – an oceanic environment surrounded by national forests. The zero SST trend at Seattle is not unusual among the west coast stations, but serves to illustrate the variability in seawater temperature trends from place to place. Seward is more influenced by the Pacific Decadal Oscillation, and care must be exercised when least-squares fitting a linear equation to oscillatory data as a trend will be calculated depending on the phase of the oscillation. West coast sites farther south are similarly influenced by ENSO (El Niño–Southern Oscillation) events and Atlantic sites by the Atlantic Multidecadal Oscillation.

Conclusion

This entry demonstrates the complex nature of water temperature change in the coastal United States using an inhomogeneous dataset. As with sea level change and other indicators of climate change, SST is seen to be site specific and that it is poor scientific practice to extrapolate to other regions of Earth. It also shows the challenge and value of data archeology (Maul et al. 2001). Many climatic records are not yet digitized and may be deteriorating or are already lost. While these data may not improve clarity in the climate change debate, they offer an important independent opportunity to learn more about the evolving nature of our planet's geophysical history.

Coastal Upwelling and Downwelling

Dilip K. Barua
Coastal, Port and Marine Engineering, Vancouver, BC,
Canada

Definition

Coastal upwelling and downwelling refer to the upward and downward transports of water mass, respectively. These vertical fluxes are the results of mass balance and are caused by the horizontal water motions of divergence and convergence. They occur in various scales of sizes and durations. Coastal upwelling is more noticeable because it brings cooler subsurface water upward to the surface in the case of a thermally stratified water column and is accompanied with primary productivity and abundance of fish resources. The phenomenon has considerable economic significance because it affects fisheries, weather, and oceanic currents in many parts of the world. This has prompted much interest in research on upwelling systems around the world. Some executed in the 1970s, including those under the umbrella of Coastal Upwelling Ecosystems Analysis (CUEA), were compiled through an International Symposium on Coastal Upwelling (Richards 1981). The upwelled water often forms a plume with fronts that can be identified by remote sensing technologies.

Upwelling and downwelling scales vary from localized episodes to large ocean areas. Upwelling speeds are very low and vary from 1 to 10 m/day, but upwelling regions cover thousands of square kilometers.

The following sections describe the physics and types of coastal upwelling and downwelling systems, major places of their occurrence, environmental consequences, mathematical models of upwelling motion resulting from longshore wind stress, and measurements.

Physics and Types

The upwelling and downwelling processes can be discussed under four fundamentally different initiation mechanisms.

Longshore Wind

The most important episodes of coastal upwelling and downwelling, in terms of size, duration, and economic importance, occur due to longshore wind. When wind blows parallel to a long shoreline for a considerable period of time (for a steady state to develop), a dynamic balance is established between the wind stress on the water surface and other hydrodynamic terms in the equation of motion. Figure 1 illustrates schematically the process of coastal upwelling development due to longshore wind. Two simplifications of the hydrodynamic equation can best explain the cross-shore motion and the resultant episodes of upwelling or downwelling. The first is popularly known as the Ekman (Swedish oceanographer Vagn Walfrid Ekman, 1874–1954) transport that results from a dynamic balance between the wind-induced frictional force at the water surface and the Coriolis (French mathematician Gustave de Coriolis, 1792–1843) force. Ekman first introduced this concept (Ekman 1905) to explain quantitatively the ice drift observations of Nansen (Norwegian explorer and scientist Fridtjof Nansen, 1861–1930) in 1893. Due to a balance between these forces, a mass transport of water takes place in the surface layer, which is directed to the right of the blowing wind in the Northern Hemisphere (to the left of the blowing wind in the Southern Hemisphere). Depending on the wind direction relative to the shoreline, water level is lowered or elevated along the shoreline, and mass conservation requirement causes vertical motions of upwelling or downwelling, respectively. For the northwesterlies along California and Oregon coast, this process creates an offshore transport of water mass, and underwater upwells to the surface (McEwen 1912) along the coast. The second simplified explanation of the same motion is based on a geostrophic balance between the pressure gradient force induced by cross-shore Ekman transport and the Coriolis force. The pressure gradient force arises due to the development of a slope in the water surface (Fig. 1).

Coastal Upwelling and Downwelling, Fig. 1

A schematic indication of the coastal upwelling processes initiated by longshore wind.
(a) Plan. (b) Elevation

Further discussion on these processes is given in the section on mathematical models of coastal upwelling and downwelling.

Offshore and Onshore Wind

On a more localized scale, upwelling and downwelling also occur due to offshore and onshore winds. Onshore winds pile up water along the coast, and downwelling occurs to satisfy the mass conservation requirement. The opposite happens, when an offshore wind lowers the water surface at the coast and the underwater upwells to the surface. Thomson (1981) and Henry and Murty (1972) reported occurrence of upwelling due to an offshore wind in the Departure Bay of Strait of Georgia. They found that due to upwelling, surface water temperature dropped by 4 °C within less than 24 h of offshore wind blowing. Field et al. (1981) measured upwelling and downwelling episodes in response to offshore and onshore windstorms, respectively, in a kelp bed in southern Benguela off Cape Peninsula in South Africa.

Underwater Ridges, Shoals, and Large-Scale Bedforms

When interrupted by underwater ridges, shoals and large-scale bedforms, the horizontal flow upwells to the surface in the form of a surface boil. Such local upwelling, especially when associated with large horizontal current, may occur in many places in response to large discontinuity of the seabed. Thomson (1981) reported several upwelling episodes in many passes of the Juan de Fuca Strait and Strait of Georgia along British Columbia coast.

Open Ocean Divergence and Convergence

From June to October, the southeast trade winds cause upwelling in the equatorial Pacific (Thomson 1981). The Coriolis force deflects the trade wind generated South Equatorial Current to northward in the north of the equator and to southward in the south of the equator. A belt of divergence, known as

equatorial divergence, is thus created that prompts upwelling of cold underwater to the surface. A similar divergence is caused at about 10° N latitude in response to Northeast Trade Winds. As a different process, divergence also occurs due to a moving pressure field associated with cyclones. A cyclonic low-pressure system causes surface water divergence, and upwelling occurs around the eye of the cyclone.

Geography

The following areas are some of the notable large-scale upwelling regions in the world (Bowden 1983; Smith 1983). These are the regions associated with anticyclonic high-pressure systems in the atmosphere:

1. In the North Pacific, between 25 and 45°N, along California and Oregon coast in response to equatorward California Current during summer northwesterlies
2. In the South Pacific, between 5 and 30°S, along Peruvian coast in response to equatorward Peru Current
3. In the North Atlantic, between 10 and 40°N, along the northwest coast of Africa in response to equatorward Canary Current
4. In the South Atlantic between 5 and 30°S, along the southwest coast of Africa in response to equatorward Benguela Current
5. Along the East Coast of Africa and south coast of Arabian Peninsula in response to poleward Somali Current during the southwest monsoon

Large-scale sea surface temperature anomalies covering the whole width of the Pacific Ocean – known as the El Niño-Southern Oscillation (ENSO) – may in part be linked to upwelling events.

Consequences

Coastal upwelling is a very well-known phenomenon because of its practical interest. The important consequences of upwelling are abundance of fish resources in the upwelling region, influence on coastal climate, development of sea fog, and intensification of existing coastal current.

Very often, the upwelled water brings upward with it a higher concentration of nutrient than the resident surface water. The reason for lower concentration in resident surface water is that over time the available nutrients are used up by the growth of phytoplankton. The upwelled nutrients are usually nitrate, phosphate, and silicate salts. The enhanced nutrient content of the upwelled surface water helps the growth of phytoplankton that supports a greater zooplankton concentration. This primary productivity maintains a high fish population, and the whole interdependence of lives in the region is known as upwelling ecosystem. Most of the important marine fisheries in the world are found in regions of upwelling. Although coastal upwelling areas comprise only 1% of the total area of the ocean, they are estimated to produce more than 50% of the total marine fish harvest.

In an upwelling region, the cold upwelled water causes a drop in air temperature of the region, and sea fog develops locally in the presence of moist air. Thomson (1981) mentioned such effects along the West Coast at Oregon and British Columbia coast.

Investigations off Oregon and Washington coast showed that the broad and slow southward flowing California Current is intensified into a narrow jet of stream with speeds exceeding 100 cm/s in the upwelling region.

Mathematical Models

In this section some mathematical models are described that deal with large-scale coastal upwelling due to longshore wind. In most models of large vertical motions in the ocean, Coriolis force is balanced against different forces such as pressure gradient force, friction force, etc. In the simplest of this model, known as Ekman-Sverdrup (Norwegian oceanographer Harald Ulrik Sverdrup, 1888–1957) model of upwelling, the Coriolis force is balanced against the steady wind forcing in homogeneous water. Together with the continuity equation, the solution of the system of equations (taking x-axis across and y-axis longshore) gives the Ekman transport (Pond and Pickard 1978; Smith 1983; Bowden 1983; Stewart 2004):

$$E_x = \rho_w w L = \rho_w u D = \frac{\tau_{sy}}{f}, \quad (1) \quad \text{and}$$

where E_x is offshore Ekman mass transport (kg/m/s), ρ_w is density of water (kg/m³), w is vertical velocity (m/s) of upwell-

ing, L is length (m) across the shore of upwelling influence, u is cross-shore horizontal velocity (m/s), D is Ekman layer depth (m), τ_{sy} is wind stress (kg/m/s²) on the water surface in the longshore direction, and f is Coriolis parameter (1/s) and is given by $2\Omega \sin \phi$, where Ω is angular speed of the earth (7.29×10^{-5} radians per second) and ϕ is latitude. The Ekman layer depth is a function of wind speed and latitude. At 30° North or South latitude, a wind speed of 10 m/s would cause $D = 61$ m. But for an Ekman layer to develop, a steady wind is required to blow for the duration of a pendulum day $= 4\pi/f$. For winds at the same latitude at 30°, the required duration is about 48 h. Some of the discussed wind-induced motions were applied by Barua and Kana (1995) in the Ganges-Brahmaputra Delta coast. The wind stress shown in Eq. 1 can be estimated using the quadratic friction law as

$$\tau_{sy} = C_d \rho_a U_{10y}^2, \quad (2)$$

where C_d is air friction drag coefficient (≈ 0.0015), ρ_a is air density (≈ 1.25 kg/m³), and U_{10y} is the wind velocity (m/s) at 10 m above mean sea level in the longshore direction.

The offshore Ekman transport defined in Eq. 1 is expressed in volumetric terms known as upwelling index, UI (Bakun 1973):

$$UI = \frac{E_x}{\rho_w}. \quad (3)$$

The UI is also referred to as Bakun index (m³/s per meter along the coast). The National Marine Fisheries Service of NOAA publishes monthly summaries of upwelling indices for major upwelling regions along the US coast.

Figure 2 shows an indication of UI magnitude responding to the change in longshore wind speed. The UI is estimated using Eqs. 1, 2, and 3.

Hidaka (1954) obtained an analytical solution to the system of hydrodynamic equations that considered a balance between the Coriolis forces and the diffusive transports in the vertical and horizontal directions. From his findings, some scales of upwelling motion can be estimated:

$$S_v = \sqrt{\frac{N_v}{f}}, \quad (4)$$

$$S_h = \sqrt{\frac{N_h}{f}}, \quad (5)$$

$$\frac{w}{u} = \frac{S_v}{S_h} = \sqrt{\frac{N_v}{N_h}}. \quad (6)$$

Coastal Upwelling and Downwelling, Fig. 2 Upwelling index (UI) in response to the presence of persistent longshore wind

In Eqs. 4, 5, and 6, S_v is vertical length scale, S_h is horizontal length scale analogous to mixing length, N_v is vertical eddy diffusivity coefficient, and N_h is horizontal eddy diffusivity coefficient. Garvine (1971) made an analysis by including the longshore water slope and showed that beyond the narrow coastal boundary layer, frictional effects could be neglected.

In reality, ocean water is stratified, and a complete solution can only be obtained by taking into account all the forces. Some early contributions in this direction were given by Yoshida (1967), Allen (1973), and Hamilton and Rattray (1978). Their solutions are dependent on defining some characteristic baroclinic terms:

$$E_v = \frac{N_v}{fh^2}, \quad (7)$$

and

$$R_b = \frac{Nh}{f}. \quad (8)$$

where N is Brunt-Väisälä or buoyancy frequency and is given by

$$N = \sqrt{-\frac{g}{\rho_w} \frac{\partial \rho_w}{\partial z}}. \quad (9)$$

In these relations E_v is Ekman number in the vertical direction, R_b is baroclinic Rossby radius of deformation, z is vertical coordinate and is positive upward, h is water depth,

and g is acceleration due to gravity. Note that Ekman number is a ratio between the friction force and the Coriolis force and R_b defines a horizontal offshore scale in which upwelling occurs.

Measurements

Field measurements of surface temperature and conductivity in horizontal and vertical directions and anomalies of these parameters from the expected variation provide a quantitative indication of upwelling and downwelling. Some examples of the stable expected variation in the vertical direction (measured positive upward) are (1) a positive temperature gradient, (2) a negative salinity gradient, and (3) a negative density gradient. Any deviation from such stable gradients is an indication that upwelling or downwelling processes exist or are going to be initiated. Visible and infrared satellite remote sensing of color and temperature are also used to identify and show the dynamics of upwelled water (Chase 1981; Petrie et al. 1987).

Summary

This entry discusses coastal upwelling and downwelling phenomena that occur ubiquitously in many coastal waters. By defining the parameters, this entry describes the physics of the processes together with mathematical models. An estimate is presented on the upwelling index (UI) to indicate its magnitude in response to persistent longshore wind. The

geographical distribution, consequences, and measurement aspects of the phenomena are also highlighted.

Coastal Warfare

Peter L. Guth
Department of Oceanography, US Naval Academy,
Annapolis, MD, USA

Definition

Coastal warfare involved military operations in the broadly defined littoral zone, including ground operations that involve proximity to water, naval operations that involve proximity to land, and air operations support both ground and naval operations.

Introduction

Most people live near the coast, and that concentration has prevailed far back into prehistory. As a result, military history includes many chapters on coastal warfare. Invading armies attack from the sea, and defenders build fortifications to keep them back. This recorded history starts with Homer's story of the Trojan War, and most recently includes the British recapture of the Falkland Islands, and in a new twist, the US Marines night landing in Somalia under the glare of television cameras.

Coastal warfare involves all the elements of warfare: knowledge and use of the environment (terrain, weather, and tides), fortifications and obstacles, deception and surprise, concentration of force at the decisive point, mobility, logistics, leadership, and technology. Coastal operations include naval battles, land battles in coastal plains, and sieges of coastal fortresses. Table 1 lists some important coastal battles.

Many naval battles have been fought in coastal waters, both because of strategic considerations and the need to support land operations. Two classical battles exemplify these operations. In 480 BC, the Greek fleet defeated the Persians at Salamis. The Greeks used constricted coastal waters to negate the size advantage of the Persian and Phoenician ships, and the naval victory ended the Persian invasion. In 31 BC, Octavius blockaded Marc Anthony's fleet at Actium on Greece's western coast. Anthony's fleet finally sortied with 220 heavy ships fighting 260 lighter ships. The

bloody but indecisive fighting ended when Cleopatra fled with 60 ships. When Anthony followed, his remaining ships despaired and Octavius won the battle that made him sole leader of Rome.

Coastal plains often provide key avenues of approach. In 490 BC, the Spartans and allies defended the pass at Thermopylae to stop the Persian advance along the coast. Betrayed when the Persians learned of a path around their positions, the Spartans conducted a heroic and doomed fight to buy time for the Greeks. As at Marathon earlier that year, coastal topography dictated the battle's location.

Coastal fortresses control land and sea avenues of approach. King Edward I of England created "Edwardian" castles in Wales. Five of these six classic castles had coastal locations allowing resupply and reinforcement by sea. Perhaps the greatest siege in history ended the millennium-long Byzantine empire, when the Ottoman Turks cutoff Constantinople by land and sea. Until the very end, the defenders hoped for relief from the sea. Improvements in technology have decreased the value of fortresses, and such sieges have become much less frequent, but the potential still exists for urban siege warfare in a coastal setting.

Coastal Warfare, Table 1 Selected coastal battles

490 BC	Marathon	Athens defeated landed Persian force on constricted coastal plain
490 BC	Thermopylae	Persians annihilate Spartans defending a choke point along the coastal plain
480 BC	Salamis	Greek naval forces defeat Persians in coastal water where the Persians cannot take advantage of larger ships
31 BC	Actium	March Antony's naval force defeated while trying to break out of blockade by forces of Octavius
1274, 1281	Mongol invasions of Japan	Two invasions defeated by typhoons
1453	Fall of Constantinople	Ottoman siege of Byzantine coastal capital, cutoff both by land and sea
1759	Quebec	British assault force landed at night, scaled Abraham Heights, and captured city
1915	Gallipoli	British land at multiple locations but cannot advance inland and eventually withdraw
1943	Tarawa	US forces capture small and heavily defended Pacific atoll
1944	D-Day invasion of Normandy	Allied forces unleash the largest amphibious assault ever on German defenders
1950	Inchon	UN forces broke out of the Pusan perimeter with amphibious landing far behind enemy line
1982	Falkland Islands	British recapture islands using naval and amphibious forces without any nearby land base

Amphibious Assaults

The amphibious assault in the face of a defended beach marks the culmination of coastal warfare. It requires cooperation among army, navy, and air force units, and reached its highest development during World War II. As late as World War I landings at Gallipoli used standard ships and small boats to land troops. In the early 1930s, the Japanese developed landing craft with a bow ramp. World War II saw the development and fielding of specialized landing craft and amphibious vehicles (Table 2). Four different theaters saw amphibious landings: leapfrogging from New Guinea to the Philippines (Fig. 1), island hopping in the Central Pacific, the Mediterranean theater movements from North African to Sicily and finally Italy, and the largest single amphibious operation in Normandy.

In 1950, UN forces in Korea staged a repeat of the World War II Pacific landings, with old landing ship tanks (LST) and many Marine veterans recalled to active duty. On environmental grounds Inchon presented an unlikely site. A narrow river channel and wide mudflats restricted ship operations. A 10 m tidal range restricted the landing to a few days each month. Surprise and impeccable execution overcame environmental drawbacks to make the Inchon landings a turning point in the Korean War.

Technology improvements have greatly increased the ability of large navies to successfully land forces on a hostile beach. Helicopters, and specially configured aircraft carriers to support them, allow airlifting of troops and bypassing of coastal defenses. Parachute and glider units filled this role in

Coastal Warfare, Table 2 Selected amphibian vehicles of World War II

Acronym	Name	Capabilities	Number produced
DUKW	Amphibious truck "Duck"	2.5 tons, 25 soldiers five knots at sea, or 80 km/h on land	20,000
LVT	Landing vehicle tracked-"amtracs," "amphtracs," or Alligator	8 m long, 6.5–7.5 knots; additional 2,850 armored LVT (A)	15,501
LCVP	Landing craft vehicle, personnel	3.6 tons of cargo or 36 soldiers	23,398
LCM	Landing craft, mechanized	15 m, one medium tank	11,392
LCI	Landing craft, infantry (large)	48 m, 200 soldiers two gangways instead of bow ramp	1,051
LCT	Landing craft, tank	Six medium tanks	1,435
LST	Landing ship, tank	100 m, 20 Sherman tanks; max. speed 11.5 knots; 1,490 tons; 26 lost in action and 13 in accidents	1,051
LSD	Landing ship dock	4,490–4,546 tons	18

Coastal Warfare, Fig. 1 LST (left) and LCVF (right) in the Philippines during World War II (Photo: M. Schwartz)

World War II landings like Normandy, but the helicopters can return to the ship and bring in additional troops and supplies ashore as needed. Squared-off bow ramps have been replaced with extendable ramps that allow a hydrodynamic bow and greatly increase the cruising speed of the amphibious ships while still allowing roll-off of assault vehicles. Large landing ship docks (LSDs, over three times the size of the 18 built during World War II) feature a large docking pool that can be flooded, allowing smaller amphibious vessels to rapidly float away to begin the assault. LCACs – landing craft air cushioned – use jet engines to float on a cushion of air, riding rapidly over the waves and obstacles up to 1.2 m high, and up onto the beach. Only one conflict since 1950 has tested the new technology, the British recapture of the Falkland Islands in 1982. When the Argentines attacked without warning, budgetary cuts left the British without a full complement of new amphibious equipment. Success relied as much on rapidly requisitioned and modified commercial vessels as on specialized naval vessels. In the First Persian Gulf War, the American amphibious forces had a diversionary role without actually performing a landing, and the new equipment and doctrine did not receive a battle test.

Military principles of amphibious assault mirror those of any offensive action. The attacker must mass forces at the critical location, and rapidly exploit the advantage. In many cases, this proves relatively easy to achieve, because the defender must spread forces over a large area and many beaches. The danger of mistaking a diversionary landing for the main attack always dulls defender reactions, allowing the attacker to exploit the initial numerical superiority on the landing beaches. Throughout history, many defenders have decided that beaches cannot be defended, and have kept large forces in reserve to fight a mobile defense once the situation becomes clear. German and Japanese attempts to fortify the beaches never stopped the attacker at the water's edge in World War II.

The key to the offense becomes rapid exploitation of the initial numerical advantage; failure here doomed the Gallipoli

landings in World War I, and led to stalemate after the Anzio landings during World War II. In contrast, the 1759 British capture of Quebec resulted from a nighttime landing, and an immediate scaling of cliffs the French had considered impassible. Rapid exploitation requires good planning, forceful leadership on the beach, and the ability to rapidly reinforce the beach. In almost all opposed landings, units in the first wave become militarily ineffective. Despite planning and rehearsals, boats land units at the wrong place and destroy unit integrity, and casualties decimate units. Junior leaders and individual initiative can carry the assault well inland and secure the beachhead, but the strategic goals of the invasion require that additional units be rapidly landed with unit integrity and supporting armor, artillery, and air defense support. Units in the follow-on waves must seize the initiative and expand the beachhead before the defenders can respond and mass their units.

Concurrently with the follow-on combat units, the attacker must land supplies to keep the units on the beach moving inland. At Gallipoli, the British had trouble keeping units supplied with water, and despite multiple successful landings at different locations and times they never exploited the initial success to expand the beachheads. At Inchon, the large tidal range required that LSTs be beached overnight to unload. Beached LSTs provide a tempting target, a necessary risk because assault troops need heavy vehicles and supplies. Logistics remain important until ports can be captured. Allied artificial harbors in Normandy failed when a major storm damaged the structures, increasing the time supplies had to come over the beach.

Environmental Considerations

Requirements for logistical support and combat reinforcement often dictate the time of a landing. A significant tidal range usually restricts landings to a few days each month, with two tides during daylight hours. The first tide near

sunrise brings in assault waves, and the next tide 12 h 30 min later brings supplies and a second wave. Depending on conditions, planners may prefer low or high tide. At Normandy, the assault came at low tide. This exposed obstacles in the surf zone, but combat engineers had to neutralize obstacles with the tide rising faster than obstacles clearance. At Inchon, planners chose high spring tide so assault vehicles could get to the seawall without getting mired in the mudflats. Neap tides might be selected to avoid the extremes in tidal range, and insure there is enough water to get over obstacles even at low water. Poor knowledge of the tides at Tarawa led to problems because the reef grounded many assault vessels, and there were not enough amphibious tractors to drive over the reef and up out of the water, but a strategic need for speed led planners to accept the risks. At Tarawa, the actual tide encountered did not correspond to either predictions or later hind casts, demonstrating the large effects of meteorological conditions with a tidal range of 1.2–1.9 m. Depending on location, favorable windows can be either two weeks (Normandy) or four weeks apart (Inchon). Tidal currents also influence the assault timetable, since at Inchon the maximum current speed equaled the speed of many amphibious assault vessels.

Geologic conditions for assault beaches generally require low slope and firm sediment. On a reflective–dissipative continuum, this generally places assault beaches in the middle of the spectrum. Assaults cannot target beaches backed by cliffs because there these lack easy egress, although landings at Quebec in 1759 and the American Rangers scaling cliffs at Normandy show that even this rule can be violated to achieve complete surprise or to provide supporting assaults. Moderate slopes offshore allow amphibious vehicles easy egress from the water, and moderate slopes ashore allow rapid expansion of the beachhead. The landing beaches at Gallipoli were small sandy pocket beaches along a coast that generally provided steep terrain right up to the water. Extreme low slopes generally must be avoided, because they come with small sediment sizes that will not allow heavy military vehicles to operate and rapidly exit the beach. The landing at Inchon came at high tide to avoid extensive mudflats; the selected “beaches” allowed the landing craft to get to the base of a seawall and minimized problems on mudflats. Favorable geologic conditions accompany favorable wave conditions, as low slopes correlate with smaller wave heights. Assaults also generally try to avoid offshore reefs. At Tarawa, the landing craft approached from inside the lagoon, but grounded on the reef and dropped Marines into the water where many drowned between the reef and shore. Other abandoned gear to get ashore, and emerged without weapons or supplies.

Weather always affects amphibious operations. Mongol invasions of Japan in 1274 and 1281 ended in defeat when intense cyclones destroyed much of the fleet. The Japanese called these *Kami-kaze*, or “divine winds,” and used the

term during World War II for suicide attacks, many at ships supporting amphibious landings. The D-Day landings had to wait 1 day, and nearly had to wait 2 weeks for favorable tides, because of a severe Atlantic storm. The Inchon fleet suffered minor damage from one typhoon while preparing in Japan, and put to sea a day early to avoid a second typhoon. For both D-Day and Inchon landings, correct favorable weather predictions by the staff meteorologist allowed the invasions to proceed without having to wait weeks for favorable tides.

While defenders have put obstacles in the water and along the beach to slow or stop the attackers, and dug reinforced positions for troops and weapons, they still defeated no major landings in World War II. Conversely, despite massive naval and air bombardments preceding most of the landings in World War II, attackers never dislodged and rarely seriously disrupted the defenders until assault boats hit the beaches. This paradox has led many military thinkers to assert that a mobile defense back from the beaches will work better than building the Maginot line at the shore, while for the attackers, a relatively short bombardment maintains surprise while achieving almost the same effect as a much longer bombardment.

Supporting landing operations can be among the costliest naval actions. During the Gilbert Islands campaign, the Marines lost 1,115 dead and missing on Tarawa. The sinking of the escort carrier *Liscome Bay*, supporting an army landing, led to the loss of 644 men. The largest naval battle ever fought, at Leyte Gulf, occurred when the Japanese attempted to destroy the forces landing in the Philippines. US losses included two escort carriers, including one lost to kamikaze. During the invasion of Okinawa in April 1945, kamikaze attacks sank 36 ships and landing craft. In the Falklands campaign, the British saw 9 of 23 frigates and destroyers either sunk or seriously damaged.

The SEAL (Sea, Air, and Land) Teams date only to 1970, but have become respected both in the military and Hollywood. Their primary missions involve military special operations along coastlines, but they often serve as general purpose special operations troops in non-coastal environments.

Twenty-First Century Developments

Coastal warfare in the twenty-first century has not involved conflict between nation states, but has seen three trends: combatting piracy, construction of artificial islands, and challenges in selecting appropriate technology. Recent piracy has involved three major hotspots: oil production areas near Nigeria, the choke points in sea routes through the Philippine and Indonesian archipelagoes, and the Somali region. Somali piracy, starting in 2005–2008 in coastal waters, peaked

in 2011 and brought significant ransom money to an impoverished country with no effective government. In response to a coordinated multi-national naval effort, pirates initially responded by going up to 2,400 km offshore in small, fast boats, before being brought under control in 2012. Periodic flare-ups, and the lack of improvement for the Somali state, suggest the continued threat of piracy, and a continued naval mission.

The South China Sea sits on one of the world's busiest shipping routes leading to the piracy hotspot in the Philippine and Indonesian archipelagoes, and has seen recent military activity including small scale armed clashes. China has been building a "Great Wall of Sand" of artificial islands, dredged to create land and building port facilities, air fields, and other military facilities in the Spratly Islands to press claims for fishing, possible oil and gas reserves, and as general territorial assertions. Other countries, with longer established territorial claims, have responded in cheaper fashions, such as the Philippines beaching the LST Sierra Madre on Second Thomas Shoal and sending a squad of marines to inhabit the rusting World War II ship that previously served in the US and South Vietnamese navies. This cat and mouse game among some of the most productive coral reefs in the world has environmental, legal, political, and military implications.

Piracy and monitoring territorial claims complicate the job of navies, which must prioritize procurements to deal with competing missions. Recognizing the importance of the coast environment, in the late 1990s the US Navy began developing the Littoral Combat Ship (LCS), which most navies would classify as a corvette. The design featured easy to reconfigure modules for different roles, including anti-submarine warfare, mine countermeasures, anti-surface warfare against small boats, but also had to handle intelligence, surveillance and reconnaissance, homeland defense, maritime intercept against piracy, special operations, and logistics missions. The LCS suffered from mission creep, cost overruns, reliability issues, and questions about survivability in combat, leading to reductions in the number of ships to be acquired. In 2015, the Navy decided to change future procurement to a frigate class as it continues to balance coastal warfare requirements with deep water missions requiring larger ships.

Conclusion

Even as active coastal warfare operations have become rare, military forces must acquire specialized hardware and train to fight in an increasingly complex environment. Population migration to the coastal regions continues, as the risks from rising sea level and global climate change intensify, makes the coastal environment critical to militaries around the world.

Coastal Wells

Yaacov Nir
Rehovot, Israel

And he looked, and saw a well in the field, and behold, three flocks of sheep were lying there beside it, for from the well they watered the flocks. Now the stone on the mouth of the well was large.

Genesis 29, 2

When all the flocks were gathered there, they would then roll the stone from the mouth of the well...

Genesis 29, 3

Historical Background

Water in arid and semiarid land is one of, if not the most important and vital factor, for the existence of people,

livestock, and farming all along the history of mankind. Therefore, in many regions where freshwater was not available, occupation was very difficult and much sporadic if at all. In general, people were dependent on permanent water sources such as springs or rivers that supplied water all year round, and temporary sources such as seasonal rivers, natural water cisterns, etc. Later, when agricultural and farming irrigation systems were developed, an immense need for larger water quantities existed. Throughout history, when there has been a necessity and demand for expansion of settlements, either as a result of political pressure or due to the growth in population, people moved (to their sorrow), from the prolific and rich water regions into much poorer areas.

Coastal areas in general, and more specifically the near-littoral zone, reached an ever-growing importance when the sea became another nutrient source to the communities of the gatherers and hunters. As a result, they looked for new water resources, preferably natural, and if these did not exist, they searched and created artificial sources.

In arid and semiarid regions where natural water sources are very scarce, settling was totally dependent on their talent to either transport water to these regions, or locate and discover other sources, mostly underground. The existence of ground-water at a relatively shallow depth below the surface in the nearshore region permitted water exploitation through well digging at least as early as the Pre-Pottery Neolithic Period (ca. 7900 years BP; Galili and Nir 1993). This period parallels the beginning of the development of canal irrigation systems in China and Anatolia (Hübener 1999).

There is no doubt that during the early periods of humanity, people experienced seasonal living along the coast

(Oren 1992), in regions where mountains reach the coastal zone, in most cases where there had been no water problem. Springs or river water easily covered the daily needs of people and their livestock. While in shallow relief or hilly coastal plains, in those semiarid lands where no springs or rivers exist, the water problem was very crucial to their survival.

Coastal Water Wells

At a certain stage of development, people discovered the fact that fresh or semi-fresh water may be reached very easily by digging shallow holes on a sandy beach quite close to the coastline (perhaps in imitation of animal behavior). It is assumed, although there is very little chance of finding any evidence at all, that this method was practiced for a very long period at much earlier stages before digging of water wells commenced.

The oldest known well in Israel is found at 10–12 m. water depth in an Atlit Pre-Ceramic Neolithic village, located offshore, opposite the southern flank of Mount Carmel (Galili et al. 1988; Galili and Nir 1993; Nir 1997). This well is about 5 m deep, mostly built of stones. It was found in a relatively large prehistoric site with many dwellings and other village installations. The well, dug in a clayey soil reached, at its lower part, a permeable carbonate cemented quartz-sandstone layer, the Pleistocene “kurkar” rock, which is known to contain a very prolific high-quality aquifer.

The majority of the historical wells are dug as a vertical pit, having a cylindrical shape, with inner diameters varying from

Coastal Wells, Fig. 1 A typical Anti I Man coastal well at Tell Ashqelon, located on the southern coast of Israel (Photo: Y. Nir)

80 to 200 cm (Forbes 1955; Nir and Eldar-Nir 1987, 1988). Wells of this type are technically constructed from top to bottom, layer after layer, strengthening its.

walls with local stones, undressed in the old wells, but nicely dressed and fit with the well's round shape in the more "modern" wells from the Hellenistic and Roman periods and on to the present.

The water sources of the coastal wells depend on the ground water table, water flowing from inland higher topography to the drainage basin—the sea. This water table fluctuates with changes in sea level that fully controls its level.

In the coastal plain of Israel, and no doubt in similar geologic terrain elsewhere around the Mediterranean and other coastal regions, ground-water has an average slope of about 1/1000, and its surface is almost linear (Kafri and Arad 1978). Many sub-recent wells were dug along the coastal plain of Israel, most of which are in the nearshore strip. One of the most famous sites, where a high concentration of wells is found, is at Tell Ashqelon, located on the southern coast (Nir 1997). More than 50 water wells of ages from Roman to the twentieth century were mapped there (Fig. 1).

Water wells of the dug-pit method have been in operation up to the present time, mainly in underdeveloped regions. Wells of different shapes, construction materials, depth, etc., exist along most of the world coasts, located in all regions where the ground water table is close to the surface. Their importance in the developed countries, has dropped, while in the developing countries where there are no other natural sources they are still of high importance to the coastal population.

Coastal Wind Effects

Terry R. Healy
Earth Sciences Department, University of Waikato,
Hamilton, New Zealand

Wind can have several effects on the processes influencing coastal geomorphology. These include wind stress on the water surface in major storms, such as hurricanes or typhoons, inducing short-term above normal sea elevations or storm surge, short "choppy" waves in estuaries and fetch-limited harbors, downwelling and upwelling processes in the coastal oceans, and sea breeze effects.

Storm surge is caused by the frictional wind stress on the water surface inducing a current in the surface water. Empirically, the resulting current in the top few centimeters of the sea surface will be about 2% of the wind velocity (Komar 1976). For Class 5 storm (hurricane) winds, a considerable mass transport is advected along the sea surface waters in the wind direction, so that onshore storm winds force the seawater up against the land. Of course this occurs concomitantly with large, wind-forced, storm waves. The total wind effect is therefore a combination of both the direct wind stress effect and the indirect wave run-up effect. Storm wind stress effects are maximized over broad shallow continental shelves and semiencloded seas, such as the Gulf of Mexico, the North Sea, and the Baltic Sea, where extreme surge effects can raise the still water level by ~5 m and flood over the low-lying barriers, estuarine wetlands, and coastal land. The storm surge effect enhances the beach erosion process along open sandy duned coastlines by raising the water table in the beach and lowering intergranular friction between the sand grains, so that the pore water pressure from the raised water table induces the sand from the lower beach face to flow out into the surf zone. But wind-generated surge also piles up

Terry R. Healy: deceased.

tidal waters inside estuaries, tidal inlets, and river mouths, often leading to saline flooding of adjacent low-lying coastal land. As a result of the onshore winds and storm surge, the tidal cycles within the estuaries are altered to a much higher than normal tides and reduced low tide.

Short steep, “choppy” waves are generated by fetch-limited winds inside estuaries and semi-enclosed seas. These “choppy” waves have a number of effects including stirring of the bottom muddy sediments in the shallow near-shore creating the characteristic high muddy suspended load “turbid fringe” observed around shallow estuaries on windy days. These waves may even generate “fluid” mud in muddy estuarine environments from the constant bottom agitation of the loosely cohesive bottom mud sediments. Wind-forced choppy waves in enclosed bays, on top of a storm surge, result in erosion cutback of low terraces and marshland above the normal high tide levels, and the lagoonal shore of barrier islands and spits—this is the prime mechanism for shore erosion within sheltered harbors and estuarine lagoons.

Downwelling and upwelling in the coastal zone are largely wind-generated processes (Fig. 1). These processes have marked, but often overlooked, influence on the diabathic (cross-shore) sediment transport. For the case of significant onshore winds blowing for some hours, surface waters are forced up against the beach and dunes, raising the still water level at the beach. As a requirement of continuity, the onshore surface current in turn generates a bottom return current (downwelling). Thus sandy sediment grains initially eroded off the

beach in a storm, when uplifted by the bottom orbital motion of the waves, are acted upon by the downwelling current as they fall back to the seafloor, and thus become transported offshore, typically to “closure depth.” Conversely, with consistent significant offshore winds, wind stress on the sea surface forces the surface water out to sea, and lowers the still water level. This generates an onshore-directed bottom return current (upwelling), and as the longer period (non-storm) swell waves uplift the bottom sediment, it is transported onshore to the beach, facilitating beach face accretion, and rapid rebuilding of the beach berm. Of the two processes, the latter likely transports bottom sandy sediment at a greater rate because the longer period waves have greater bottom orbital

velocities which uplift more sediment. It is often observed that beach recovery at the end of a storm (when winds reduce in strength and change to an offshore direction) is more rapid than the loss of sand from the beach during the erosion phase.

Sea breeze effects arise from the thermal heating of the land generating a steady onshore wind. The effect of sea breeze on beach morpho-dynamics has been studied on the Western Australian coast, where sea breezes are some of the strongest in the world. Here the sea breeze cycle is an important influence on beach processes, with onshore winds reaching magnitudes >8 m/s. Masselink and Pattiaratchi (1998) researched the effects of the sea breeze on the near-shore processes, demonstrating how with the onset of a strong onshore sea breeze of 10 m/s, the root mean square (rms) wave height increased from 0.3 to 0.5 m, the wave period

Coastal Wind Effects, Fig. 1 Effect of wind generation inducing coastal upwelling and downwelling and associated diabathic sediment transport

decreased from 8 to 4 s, and mean cross-shore flows reached velocities of 0.2 m/s directed offshore. The short period sea breeze-generated waves became superimposed on the background swell. During the sea breeze event, nearshore sediment resuspension became almost continuous, and cross-shore transport was directed offshore. But in addition, the sea breeze affected the beach longshore transport rates when it approached the coast obliquely, and the longshore-suspended sediment transport rate increased by a factor of 100. These sea breeze-induced hydrodynamic changes were associated with erosion of the beach face, and deposition in the surf zone, with a consequent flattening of the profile. The effect was similar to a storm of medium intensity.

Coastline Changes

Eric Bird
University of Melbourne, Melbourne, VIC, Australia

Definition

Coastline changes (here defined as changes on the high-tide shoreline) can be mapped and measured on various coastal sectors over time scales ranging from a few hours or days (related to tidal cycles, weather events, earthquakes, or tsunamis) to long-term trends over decades or centuries.

Evidence of Coastline Change

Evidence of coastline changes can be obtained from comparisons of dated historical maps, charts, air photographs, and satellite imagery with the present coastal configuration. Such

evidence is available on many coasts over the past century, but in some countries, such as Britain and Denmark, maps and charts surveyed around the beginning of the nineteenth century permit the determination of changes over longer periods: Houston and Dean (2014) used measurements of shoreline change on the east coast of Florida since the mid-1800s to demonstrate long-term beach accretion. In the Mediterranean region, and locally elsewhere, there is sporadic evidence of coastline changes over periods of at least 2,000 years, using historical descriptions and dated archaeological sites. On some coasts there is geological evidence of changes over the past 6,000 years, since the Late Quaternary marine transgression brought the world's oceans to approximately their present levels: cliffed coasts have receded and depositional coasts have advanced, and some coasts show evidence of alternations of advance and retreat during this period.

Advance or retreat of a coastline may result from combinations of erosion and deposition, emergence and submergence (Fig. 1). Coastline changes are usually expressed in linear terms, as the extent of advance or retreat measured at right angles to the land margin, but they can also be considered in areal terms, as the extent of land gained or lost on a coastal sector, or volumetric terms, as the quantity of material added to, or lost from, the coast. Measurements made over varying periods are commonly averaged as gains or losses per year, but coastline changes may be sudden or intermittent rather than steady and gradual. Attempts have been made to

Coastline Changes, Fig. 1 Analysis of coastline changes, based on Valentin (1952), Z-Z' indicates a stable coastline where erosion has been offset by emergence or deposition by submergence, or where no changes have taken place (O) (Copyright-Geostudies)

document the advance or recession of coastlines in several countries: the Royal Commission on Coast Erosion in Britain (1907–11), the National “Shoreline” Study in the United States (US Army Corps of Engineers, 1971), and the survey of the Netherlands coastline by Edelman (1977); and in 1984 the International Geographical Union’s Commission on the Coastal Environment completed a global review of coastline changes over the preceding century (Bird 1985). More recently there has been monitoring of changes on particular coastlines using remote sensing and photogrammetry, but this has not yet been pursued systematically around the world’s coastline. In the absence of another global review the indications are that changes during the past 30 years have been mainly on the pattern identified previously, apart from large-scale coastal land reclamation projects, particularly in Asia.

Some coastlines have changed very rapidly (advance or retreat >100 m/year), but changes of more than 10 m/year are unusual, and few have changed by more than ± 1 m/year. If, as is predicted, a worldwide sea-level rise develops and accelerates as a consequence of global climatic warming resulting from the enhanced greenhouse effect, submergence and erosion will become widespread, and coastline changes are likely to intensify (Bird 1993). Coastline changes can be considered in the following categories.

Cliffed Coastlines

Cliffs in hard, massive rocks have changed little over the past century, even where they are exposed to stormy seas, but cliffs in soft materials can be cut back very rapidly. Sample rates of cliff retreat were tabulated by Sunamura (1992: Appendix 2). Recession of up to a meter a day has been measured on cliffs cut in unconsolidated volcanic ash, as on the Isla San Benedicto, off the Pacific coast of Mexico, and cliffs cut in

alluvium and peat weakened by seasonal freeze-thaw oscillations have retreated up to 100 m in a few summer months before a winter cover of snow and ice briefly stabilized them. On parts of the Polish coast, cliffs cut in glacial drift deposits have shown an average recession of a meter a year, but have lost up to 5 m in a single storm, and similar rates have been documented on the east coast of England, notably on the Holderness cliffs, also cut in glacial drift. Recession of cliffs cut in soft formations is often accelerated by slumping and erosion by runoff after heavy rain or from melting snow. Storms have modified structures such as stacks and natural arches on cliffed coasts, as on the Port Campbell coast in Victoria, Australia, where several of the stacks known as the Twelve Apostles have disappeared in recent years and natural arches collapsed at London Bridge in 1990 (Figs. 2 and 3) and Island Archway in 2009.

Glaciated Coastlines

Where glaciers and ice sheets reach the sea, as in Icy Bay, Alaska, southernmost Chile, and sectors around the Antarctic continent, the coastline may advance with forward movement of the ice, or retreat as the result of melting. Ice cliff coastlines have receded at rates of up to a kilometer per year in Antarctica as the result of melting and calving induced by recent climatic warming. In the Gulf of Alaska, however, rivers augmented by glacialfluvial outwash from melting ice have advanced parts of the coastline by more than a kilometer in recent decades by building deltas and prograding beach ridge plains. Rapid progradation occurred on the southeast coast of Iceland when melting of ice, hastened by volcanic eruptions, generated torrential outwash, delivering large quantities of sand and gravel to prograde beaches and build barriers and spits.

**Emerging and Submerging Coastlines**

Where land uplift has occurred the coastline has advanced. Isostatic uplift of formerly glaciated areas in Scandinavia and northern Canada has led to the emergence of former nearshore sea floors, as in the Gulf of Bothnia, where the coastlines of Sweden and Finland have advanced more than 100 m over the past century. On some sectors progradation has been augmented by shoreward drifting of sea floor sediment, notably sand from submerged eskers, to build up beaches. Sudden emergence during earthquakes has advanced coastlines on Montague Island, Alaska (1964), Talcahuano in Chile (observed by Charles Darwin during the voyage of the *Beagle* in 1835), the Orontes delta in Turkey (1958), the Makran coast in Pakistan (1945), Cheduba Island in Burma (1762), Tokyo Bay in Japan (1923), and Wellington (1855) and Napier (1931) in New Zealand. Emergence occurred during the phase of sea-level lowering between 1929 and 1977 on the coasts of the Caspian Sea, when islands expanded and became attached to the mainland, while shoals emerged as islands.

Submergence results in coastline recession, except on vertical cliffs or where it is compensated by coastal deposition. Land subsidence in the vicinity of the Mississippi has led to the submergence and erosion of former subdelta coastlines, and land subsidence in the Netherlands, augmenting the effects of a rising sea level, would have submerged a large part of the country had the coastline not been maintained by seawalls and reclamation works. Subsidence in the Venice region, due partly to subsurface compaction and the extraction of groundwater, has accelerated beach retreat on the Lido barriers and diminished the extent of salt marshes in the Venice Lagoon. Increasing depth and frequency of storm surge flooding here indicates that submergence is partly due to a rising sea level in the Adriatic. Since 1977 the Caspian Sea has been rising and the coastline receding, much of the

coastal land that emerged previously having been inundated. Sandy barriers have formed and are migrating landward (Ignatov et al. 1993).

Sudden submergence during earthquakes led to coastline recession at Anchorage in Alaska (1964), in southern Colombia (1979), at Concepcion in Chile (1960), and on the Indus delta (1819, 1845). Tsunamis following sea floor mass movements have caused sudden recession of the Valdez delta in Alaska and along the beach-fringed Ivory Coast.

A correlation has been noted between alternations of water level in the Great Lakes and the advance or retreat of bordering coastlines. During phases of falling lake level the coastline advances as the result of emergence and shoreward drifting of sand to accreting beaches, while during phases of rising lake level the coastline retreats as the result of submergence, beach erosion, and increased cliff recession.

Volcanic Coastlines

Volcanic eruptions prograde the coastlines where lava and ash are deposited, as on the southeast coast of Hawaii. They also augment river sediment loads, leading to the advance of deltaic coasts, as on the Rio Samala in Guatemala, and the progradation of beaches, as in the Bay of Plenty, New Zealand, after the Tarawera eruption in 1886 and on the south coast of Java after recurrent eruptions of the Merapi volcano.

Some oceanic islands are entirely of volcanic origin. Surtsey, off the south coast of Iceland, was built by volcanic eruptions in 1966–1967, and has since been reshaped by the rapid recession of cliffs cut in lava and ash on the more exposed southern coastline, generating sand and gravel that have drifted round to accumulate on a triangular northern foreland. The explosive eruption of Krakatau Island,

Indonesia, in 1883 left caldera-side cliffs and a surrounding mantle of ash which initially advanced the coastline, but has since been cut back as cliffs receding at up to 6.6 m/year.

Mass Movements

Coastal landslides and rock falls temporarily prograde the coastline, forming lobes and fans that are subsequently cliffed and cut back by marine erosion. This sequence has been documented at Tillamook Head in Oregon; Pacific Palisades, California; Black Ven and Fairy Dell in Lyme Bay, Dorset; Rosnaes and Helgenaes in Denmark; and on the Bulgarian and Crimean coasts of the Black Sea. On the Dorset coast erosion pin measurements have shown intermittent mudslide movements totaling 8 cm in 30 h, graded movements of about 3.5 m in 17 h and surge movements of up to 3 m in 20 min (Allison and Brunsden 1990). Some landslide lobes have persisted long enough to act as natural breakwaters, intercepting drifting beach sediment and causing local progradation, as at Golden Cap in Dorset.

Deltaic Coastlines

The arrival of large quantities of fluvial sediment at the mouth of a river has led to rapid accretion of sectors of deltaic shoreline, with rates of up to 80 m/year at the south-west Pass of the Mississippi delta and up to 70 m/year on the Irrawaddy delta. On the north coast of Java deltas fed by sediment-laden floodwaters have prograded by up to 180 m/year. Progradation results from deposition of fluvial sediment on river banks to form natural levees, prolonged seaward as sedimentary jetties, and the delivery of sand and gravel to prograde bordering beaches. In addition, there is often a seaward advance of bordering salt marshes, as on the Fraser delta in Canada, or mangrove swamps, as on most tropical deltas, and sedimentation within these eventually builds up new land at high tide level.

Even where deltas have not formed, sediment supplied by rivers can prograde adjacent coastlines. Sand from the Columbia River on the Pacific coast of the United States has been distributed northward and southward to prograde Long Beach and the Clatsop Plains. Fluvially nourished beach progradation has also occurred on the west coast of South Island, New Zealand, and in north-east Queensland.

Where the mouth of a river is diverted during a major flood, the coastline that had formerly prograded begins to recede, while new progradation develops at the diverted outlet. This has happened on the Huang He in China (1852), the Rio Sinu in Colombia (1942), the Ceyhan in Turkey (1935), the Medjerda in Tunisia (1973), and the Cimanuk in Java (1947). Artificial diversion of a river mouth by canal cutting

has had similar effects on the Brazos delta in Texas (1938), the Rioni in the eastern Black Sea (1939), the Shinano in Japan (1922), and the Cidurian in Java (1927).

Progradation of deltas and coastal plains has accelerated where river sediment yields have increased as the result of soil erosion in their catchments, due to deforestation, overgrazing, or cultivation of steep hinterlands. In Java this has led to rapid progradation of deltas in Jakarta Bay, and the Segara Anakan bay on the south coast is shrinking rapidly as the result of increased sediment input from the Citanduy river. On some coasts, progradation has followed an increase in fluvial sediment yield due to hinterland mining. Hydraulic sluicing in the Sierra Nevada a century ago led to the growth of the Sacramento delta into San Francisco Bay, and open-cast mining has resulted in beach progradation at Par and Pentewan in Cornwall, Chanaral in Chile, Jaba on Bougainville, and around New Caledonia, especially on the Thio and Népoui deltas. Reduction in fluvial sediment yield to the coast following the building of dams on rivers has led to the onset or acceleration of erosion on many deltas. The best-known example is the Nile delta coastline, which has shown recession of up to 40 m/year since the completion of the Aswan High Dam upstream in 1964. Similar erosion has been documented on the Rhône delta in France. Deltaic coastline erosion has also followed extraction of sand and gravel from river channels or the reduction of runoff by irrigation schemes, soil conservation works, and afforestation in catchments, notably in Italy, Greece, and Turkey.

Beach-Fringed Coastlines

Changes on beach-fringed coastlines result from variations in the rate of supply of sediment from various sources or in losses from the beach system, as shown in Fig. 4. Progradation of beaches and growth of spits supplied with sand and gravel from the erosion of nearby cliffs is well illustrated on coasts dominated by glacial drift deposits, as on Puget Sound on the west coast of North America, New England and the Canadian Maritime Provinces on the east coast of North America, and the coasts of the North Sea and the southern Baltic. Changes in the configuration of spits generally include their prolongation, often accompanied by recession of their outer coastlines with longshore drift of eroded sediment to their growing ends: an example is Cape Henlopen, a northward-growing spit on the southern side of Delaware Bay, on the Atlantic coast of the United States.

Construction of breakwaters to protect ports and harbors has often resulted in changes on adjacent coastlines, notably where longshore drift of beach sediment has been intercepted to cause local progradation. In some cases accretion updrift of such breakwaters has led to erosion downdrift, as at Lagos Harbor in Nigeria, but there are also examples of progradation

Coastline Changes, Fig. 4 The various ways in which sand is gained by, or lost from, a beach. When gains have exceeded losses beach progradation is likely to occur, while losses exceeding gains leads to

the lowering, flattening, and cutting back of the beach profile. Gravel (shingle) beaches show similar patterns of gain and loss, without the wind-blown component (Copyright-Geostudies)

on both sides of a harbor entrance resulting from longshore drift convergence or shoreward sediment supply, as at Lakes Entrance in Victoria, Australia.

Beach erosion can occur when the sediment supply from eroding cliffs diminishes as the result of seawall construction or stabilization, or a reduction in incident wave energy, as at Bournemouth and Brighton in southern England, the Melbourne Bayside coast on Port Phillip Bay, and Byobugaura in Japan.

On many coasts the onset of beach erosion has been due primarily to a rise in relative sea level, but as shown in Table 1 there may be other contributory causes. A recent increase in beach erosion around Port Phillip Bay, Australia, is thought to be the result of deepening the entrance from the sea by dredging to improve navigation, leading to a rise in high tide levels (Bird 2011). Beach erosion has been widespread around the world: examples of coastline advance by continuing beach accretion in recent decades are comparatively rare, many beach resorts having erosion problems, but such an advance has occurred at Seaside in Oregon, Malindi in Kenya, and Riumar on the Ebro delta in Spain. Successful beach renourishment projects have led to the advance of the coastline, as at Praia da Rocha in southern Portugal (Fig. 5).

The spilling of waste from coastal quarries has prograded beaches, as at Hoed in Denmark, Porthoustock in Cornwall, and Rapid Bay in South Australia. At Workington in Cumbria, the dumping of waste from coal mines and steel works has locally augmented beaches. On the other hand, quarrying of sand, gravel, or shelly material from beaches has not only depleted them, but has led to accelerated erosion on nearby cliffs, as at West Bay and Seatown in Dorset, Gunwalloe in Cornwall, Hallsands in Devon, and St. Ouen's Bay in Jersey.

Information supplied to the International Geographical Union's Commission on the Coastal Environment in 1972–1984 indicated that about 20% of the world's coastline consisted of sandy beaches backed by beach ridges, dunes, or other low-lying sandy terrain. Of this, more than 70% had

shown net erosion over the preceding few decades and less than 10% sustained progradation, the remaining 20–30% having been stable, or shown no measurable change. The initiation or acceleration of beach erosion was attributed to several factors, listed in Table 1. The relative importance of these factors differs from one coastal sector to another, but analysis of particular eroding beaches has shown that usually more than one has contributed. A detailed discussion was provided in Bird (1996).

Swampy Coasts

The seaward margins of salt marshes and mangrove swamps (generally close to the mid-tide shoreline) have advanced seaward where the sediment supply has been abundant, particularly on coasts sheltered from strong wave action and on the shores of prograding deltas. Sedimentation within the widening salt marshes and swamps eventually builds them up to high-tide level, so that the coastline advances. Extensive salt marsh progradation has occurred around Chesapeake Bay during the past 350 years, and has been attributed to increased sediment yields from inflowing rivers as the result of soil erosion in their catchments. Mangrove swamps have prograded on some tropical coasts, particularly near growing deltas, as on the shores of southern and eastern Kalimantan in Indonesia. On the west coast of Peninsular Malaysia, mangroves spread seaward by up to 54 m/year between 1914 and 1929 when sediment yields from agriculture and mining were high, but after dams were built on rivers and tin mining activity reduced erosion became prevalent (Kamaludin 1993). The major tsunami in the Indian Ocean in 2004, generated by an earthquake off Sumatra, caused extensive marine flooding and erosion on the coast from Indonesia and Malaysia through Thailand and India around to Somalia: the effects were diminished where a mangrove fringe persisted, but were severe where mangroves had been cleared.

Coastline Changes, Table 1 The causes of beach erosion

1. Submergence and increased wave attack as the result of a rise in sea level or coastal or nearshore land subsidence: the “Bruun Rule” (Fig. 5)
2. Diminution of fluvial sand and shingle supply to the coast as a result of reduced runoff or sediment yield from a river catchment (e.g., because of a lower rainfall, or dam construction leading to sand entrapment in reservoirs, or successful revegetation and soil conservation works), or the natural or artificial diversion of a river outlet, or because of the removal of much or all of the weathered mantle from slopes in the river catchments, exposing bare rock that yields little or no sediment to runoff
3. Reduction in sand and shingle supply eroded from cliffs or shore outcrops (e.g., because of diminished runoff, stabilization of landslides, a decline in the strength and frequency of wave attack, or the building of seawalls to halt cliff recession), or the exposure by cliff recession of formations (such as massive resistant rock, or soft silts and clays) that do not yield beach-forming sediment
4. Reduction of sand supply to the shore where dunes that had been moving from inland are stabilized, either by natural vegetation colonization or by conservation works, or where the sand supply from this source has run out
5. Diminution of sand and shingle supply washed in by waves and currents from the adjacent seafloor, either because the supply has declined (e.g., where ecological changes have reduced the production of shelly or other biogenic material), because the transverse profile has attained a concave or steeply declining form which no longer permits shoreward drifting, or because such drifting has been impeded by increased growth of seagrasses or other marine vegetation
6. Removal of sand and shingle from the beach by quarrying or the extraction of mineral deposits, or losses from intensively used recreational beaches, for example, as the result of beach cleaning operations
7. Increased wave energy reaching the shore because of deepening of nearshore water (e.g., where a bar or shoal has drifted away, where seagrass vegetation has disappeared, where dredging has taken place, or where the seafloor has subsided)
8. Reduction in sand and shingle supply from alongshore sources as the result of interception (e.g., by a constructed breakwater or groins) or interruption by the growth of a fringing coral reef or some other depositional feature
9. Increased losses of sand and shingle alongshore as a result of a change in the angle of incidence of waves (e.g., as the result of the growth or removal of a shoal, reef, island, or foreland, or because of breakwater construction or a change in wind regime)
10. Intensification of obliquely incident wave attack as the result of the lowering of the beach face on an adjacent sector (e.g., as the result of dredging, or scour due to wave reflection induced by seawall or boulder rampart construction or beach mining, or bow waves generated by ships passing through nearshore waters)
11. Increased losses of sand from the beach to the backshore and hinterland areas by onshore wind action, notably where backshore dunes have lost their retaining vegetation cover and drifted inland, lowering the terrain immediately behind the beach and thus reducing the volume of sand to be removed to achieve coastline recession
12. Increased wave attack due to a climatic change that has produced a higher frequency, duration, or severity of storms in coastal waters
13. Diminution in the caliber of beach and nearshore material as the result of attrition by wave agitation, leading to winnowing and losses of increasingly fine sediment from the beach, either landward into backshore dunes or seaward to bars and bottom deposits
14. Diminution of beach volume by weathering, solution, attrition, or impactation (e.g., by heavy vehicle traffic), resulting in lowering of the beach face and coastline recession
15. Increased scour by waves reflected from backshore structures, such as seawalls or boulder ramparts, leading to reduction of the beach that fronted them
16. Migration of beach lobes or forelands as the result of longshore drifting – there is progradation as these features arrive at a point on the beach, followed by erosion as they move away downdrift
17. A rise in the water table within the beach, due to increased rainfall or local drainage modification, rendering the beach sand wetter and thus more readily eroded
18. Increased losses of beach material due to outwashing by streams or from drains carrying an augmented discharge of water, either because of increased rainfall or from melting snow or ice, or because of natural or artificial modifications (such as urbanization) in the catchments that have increased runoff through beaches
19. Intensification of wave action where tide range has diminished, as on the shores of a bay or lagoon that has been partly enclosed by natural or artificial structures, impeding tidal ventilation
20. Erosion where driftwood deposited on the beach is jostled by wave action, leading to erosion of sand and gravel from the beach face
21. On Arctic coast beaches the removal of a protective sea ice fringe by melting, so that waves reach the beach (e.g., for a longer summer period) and subsidence due to the melting of permafrost within a beach

On many coasts the seaward margins of salt marshes and mangrove swamps have retreated in recent decades, so that they terminate in small cliffs, fronted by tidal mudflats or sandflats. In southern England and north-western France, and in New England, seaward cliffing of salt marshes is very extensive, and similar features are seen on mangrove swamps on the west coast of Peninsular Malaysia, in Thailand, and the Philippines, possibly in response to a relative sea-level rise in recent decades.

Artificial Coastlines

Many coastlines have become artificial, especially during the past century, as the result of the construction of seawalls, boulder ramparts, and other structures intended to halt erosion on cliffs, beaches, and deltas. Spits such as Ediz Hook in Washington and Sandy Hook in New Jersey, previously variable in configuration, have been armored with seawalls or boulder ramparts. Breakwaters built to shelter harbors or form

Coastline Changes, Fig. 5 The Bruun Rule states that a phase of sea level rise on a sedimentary coast will be accompanied by erosion (R) of the beach as a volume of sediment ($V_1 = V_2$) is transferred from the

backshore to the nearshore zone in such a way as to restore the transverse profile landward from D, the initial seaward boundary of nearshore sand deposits (Copyright-Geostudies)

marinas are now widespread on the coasts of North America, Europe, and the Mediterranean, and some coastal areas have been embanked and reclaimed for ports, industry, and urban development, notably in the Netherlands, China, Singapore, Hong Kong, and Tokyo Bay. Reclaimed areas are typically bordered seaward by earth banks or concrete walls, which have become extensive on the coasts of Britain, Europe, and Southeast Asia, particularly Japan, where about a quarter of the coastline is armored with seawalls and tetrapods (Walker and Mossa 1986). Artificial islands formed by deposition of sediment off Dubai in the Arabian Gulf have been reduced by erosion except where they are protected by sea walls.

Many coastlines have been modified by land reclamation: an example is Samphire Hoe, an artificial terrace constructed in 1990–1994 in front of chalk cliffs west of Dover in south-east England using rock waste excavated from the Channel Tunnel from Folkestone to Calais (Fig. 6).

The building of artificial structures is still a widely preferred response to erosion and submergence of coastlines, but increasing use is being made of beach nourishment as a means of defending coastlines against erosion, which also provides a recreational resource of scenic value.

Cliffed coastlines have been modified where roads have been built on bridges in front of them, as at Coalcliff in New South Wales (Fig. 7) and on the Muscat coast.

Coastline Changes, Fig. 6

Samphire Hoe, an artificial terrace fronting Chalk cliffs on the Kent coast west of Dover (Copyright-Geostudies)

Coastline Changes, Fig. 7 Sea Cliff Bridge, built in 2004 along the cliffed coast at Coalcliff, south of Sydney, New South Wales, Australia, to provide an alternative to a corniche road that was frequently closed by rock falls (Copyright-Geostudies)

**Summary**

Changes that occur on cliffs, coastal glaciers, volcanoes, deltas, beaches, swamps, and artificial coasts are described and analyzed. Reference is made to mass movements on steep coasts and 21 causes of erosion on beaches are listed.

Coasts, Coastlines, Shores, and Shorelines

George F. Oertel
Department of Oceanography, Old Dominion University,
Norfolk, VA, USA

Origins of Terms

The word shore comes from the middle English word *Schöre* that came from the middle low German word *Schöre*. Shore is also an archaic past tense and past participle of shear. In the German language, the verb shear is *scheren* (Betteridge 1965). *Schere* (or shear) means shearing, cutting, or a point of division. Thus, the middle English and low German *schöre* translates as the sheared line (or shoreline) between the ocean and the land. In the German language, *schöre* is a line and not a region. However, the English usage of shore (from *schöre*) became a description of the *area* adjacent to a body of water. Webster's unabridged dictionary defines shore as "land at or near the edge of a body of water" (McKechnie 1979). The term shoreline is used to describe the *line* marking the edge of a body of water.

The German language actually uses a different word to describe the strip of land adjacent to a body of water. The German word *ufer* is used for bank, shore, beach, or edge. Thus, *ufer* is more akin to the English shore, and *schöre* is more akin to the English shoreline.

The word coast comes from the middle English and old French word *coste* meaning rib, hill, or shore. In Webster's

unabridged dictionary, coast, is the edge or margin of land next to the sea. The close similarities between the words shore, shoreline, coast, and coastline have lead to many ambiguous and inaccurate usage that are unacceptable for scientific dialogue. Scientific usage of these terms are very specific and require explanations related to their description and use.

Geometric Attributes

Coasts, coastlines, shores, and shorelines have geometric characteristics that have precise denotations in scientific nomenclature. Casual usage of the words line, surface, and prism is not appropriate because they are too imprecise or ambiguous. Below are formal definitions of these terms as they should be used in scientific dialogue.

Shorelines and coastlines are lines designating the boundaries between fluid and solid media. A *line* is a one-dimensional construct used to signify the sheared edge between two different materials. A line has length but not breadth. The term coastline and shoreline are both boundary lines between water and land. The term coastline is generally used to describe the approximate boundaries at relatively large spatial scales. Shoreline is used to describe the precise location of the boundary between land and water.

Strips of land adjacent to shorelines and coastlines are called shores and coasts, respectively. Shores and coasts are bounded on one side by a body of water and on the other by a change in terrain to an upland landscape. The *surfaces* of these land strips are two-dimensional features having length and breadth but no thickness. While shore surfaces may have relief, the relief does not give the surface a thickness that implies a volume. The relief only describes elevation changes on a two-dimensional surface. The main difference between a shore and a coast is one of scale. Shores are relatively narrow strips of land adjacent to water bodies, whereas, coasts generally depict relatively broad bands of land adjacent to water bodies.

In a geologic context, processes of erosion, transportation, and deposition sculpt the relief on land surfaces. These processes involve the removal, transport, or deposition of a volume or mass of material, and imply a three-dimensional quality of the shore. The shore must be considered a three-dimensional prism when considering the processes that build or destroy it.

Shore surfaces are two-dimensional areas capping the three-dimensional shore prism. Shorelines are one-dimensional boundaries at the edge of the shore. Generally, the terms shore and coast are used to describe the prism of material below the elongate land surfaces at the edge of a body of water.

Coasts and Coastlines

The terms *coast* and *coastline* are used for describing the boundary between the land and the water at broad regional scales. The coast is a strip of land of variable width that extends from a body of water inland to a regional break in terrain features. The coastline is the line that forms the boundary between the coast and a major body of water.

At regional to global scales, the term coastline (rather than shoreline) is used to differentiate the boundaries between the land and the sea. At these scales, changes in margin shapes and boundary orientations are used to describe continents, oceans, and marginal seas. Even at smaller regional scales, coastlines are used to describe the marginal shapes and boundary orientations of estuaries, bays, deltas, barrier islands, and spits. Coastlines may be accurately portrayed on maps having global or regional scales, but the widths of lines constructed at these scales are too large to locate the precise physical position of the sheared boundary between land and water. For example, a volcanic island on a very broad-scale map may look elliptical in shape, but upon closer inspection the border between the land and the sea may illustrate a serrated boundary created by headlands and pocket bays (Fig. 1). The same effect would occur at regions of long straight coasts where the precise water boundaries of small estuaries and bays are scarcely discernible at large scales. The broad-scale maps “smooth-out” small coastal irregularities. Thus, the coastline is generally not as precise as the associated shoreline that traces the land–sea boundary at much finer detail. The coastline is a line connecting the most seaward promontories into the sea. Consequently, a length of shoreline is generally much longer than the associated length of coastline (Fig. 1).

Coasts, Coastlines, Shores, and Shorelines, Fig. 1 Hypothetical planview of a volcanic island showing the apparent shapes of the island from a broad-scale view and a close-scale view. The coastline is oval-shaped, whereas the shoreline illustrates all of the shore irregularities

Since the coast is a strip of land adjacent to the coastline its precise boundaries are indefinite and general. The coast is the strip of land between the coastline and a change in terrain to upland landscapes. The coast includes specific coastal environments or landscapes that are distinct from the upland (e.g., bays, estuaries, coastal dunes, maritime forests, maritime climates, tidal waters, etc.).

At early periods in the Earth's history, there were no images or surveyed maps to precisely locate land–water boundaries. Boundaries could only be deduced from other indirect sources of data. Coastlines from these data sources have imprecise locations with respect to their spatial and temporal setting. For example, at periods of 10^4 – 10^5 years, water volumes in the ocean fluctuate in response to the expansion or contraction of continental glaciers. Glacial waning increases the volume of the sea causing water to transgress over the land surface, while glacial expansion causes water to regress off the land surface. The vertical shift in water level produces horizontal shifts in the position of the boundary between the two media. A paleogeographic depiction of the coastline during these periods may be reconstructed using terrain slope and sea-level projections. These are generalized locations of the boundaries, rather than precise paleo-shoreline locations. A time series of coastline positions on a map may be used to illustrate the regression of water off a land surface, or the transgression of water over a land surface. Thus, temporal scaling also influences our interpretation of coasts and other large-scale areas. Since short-term events generally produce small changes to coastal landscapes, the record of these events cannot be observed at large coastal scales. At broad spatial scales, only large changes produced over long temporal intervals can be observed.

As the sea transgresses over, or regresses off a land surface, the process necessitates a lateral shift in the position of the coastline. At large spatial and temporal scales, the antecedent topography might be considered a passive surface being inundated by rising water. The process is “morphostatic,” meaning that the coastline shift is driven by flooding of a surface rather than erosional sculpting of the surface.

Shore and Shorelines

The terms *shore* and *shoreline* are used for describing the boundary between the land and the water at very fine local scales. The shore is a strip of land of indefinite width that extends inland from a body of water. The terrain of the shore is primarily composed of forms generated by active or recent marine and marine-related processes. The landscape of the shore generally has a unique plant community draped over the terrain. The landward limit of the shore is located at a boundary separating these terrains and plant communities from upland landscapes. The shore is a dynamic area that has many ephemeral forms sculptured by a variety of marine processes. The landward part of the shore that is primarily

molded by aeolian processes is called the backshore (Fig. 2). The surface of the backshore often has a succession of plants draped over a chronosequence of dune ridges between the water's edge and the upland areas. The berm and foredune areas of the backshore are located on shifting sandy surfaces that are sparsely vegetated with specialized herbaceous plants and grasses that tolerate intense light, heat, drought, burial, and salt spray. Dune ridges and swales are located on relatively stable surfaces that have dense concentrations of stress-tolerant grasses and shrubs.

Common grasses that colonize dune surfaces in warm temperate zones include sea oats (*Uniola paniculata*), American beach grass (*Ammophila breviligulata*), and running beach grass (*Panicum amarum*). Common shrubs in the swales between dune ridges include wax myrtle (*Myrica cerifera*), bayberry (*Myrica pensylvanica*), and silverling (*Baccharis halimifolia*).

The seaward part of the shore is called the foreshore, which is defined by tidal range (Fig. 2). The high-water elevation defines the upper limits of the foreshore, and the low-water elevation defines the lower limit of the foreshore (a more comprehensive description of foreshore zones is described below). The foreshore is the portion of the shore where wave-energy is dissipated on the land. The foreshore is sculptured by the dispersion and shifting of granular particles by the energy of waves and littoral currents. The resultant patterns of erosion and accretion make the foreshore one of the most dynamic areas of the shore.

Shorelines

The shoreline is a line that demarks the precise boundary between the shore and the water. Since the position of the water shifts with the elevation of the tide, then the position of the line at high tide is different from its position at low tide. On Fig. 2 it is apparent that there is a high-water shoreline at high tide and a low-water shoreline at low tide. Sea level is generally defined as the elevation halfway between the high-

and low-water elevations, and the generic “shoreline” is meant to describe the line associated with sea level, rather with high or low tide. However, during the rise and fall of the tide, there are an infinite number of shorelines between high tide and low tide.

The elevations of high tide and low tide are not constant. They are dependent on changes in the magnitudes of gravitational and centrifugal forces pulling on the water surface. Changes in the gravitational forces result from the motion and changes in the relative alignments of the Sun, the moon, and the Earth. When the positions of the Earth, moon, and Sun have additive gravitational effects, then the greatest tidal bulges occur (spring tides). A favorable alignment for gravitational addition occurs twice a month producing spring tides. However, the gravitational forces offset each other twice a month producing, small tidal ranges (neap tides). The elevations of each progressive high and low tide are different with the incremental changes in the resultant gravitational forces of the three celestial bodies. In fact, there are over 140 factors involved in the generation and alteration of the tides. The gravitational force of the moon plays a major role in tidal variations. However, the moon's orbit around the Earth is slightly irregular and it takes about 9.3 years for the plane of the moon's orbit to shift above and then below the plane of the solar ecliptic. The cycle is completed in about 18.6 years. These factors can be used to mathematically predict the tidal ranges. An average of all of the high tides and low tides over 18.6 years provides the mean-high and mean-low tide elevations for those predictions. The relationships also can be used to predict the elevations of water level at any position in the 18.6-year cycle, but it assumes no elevation changes are caused by atmospheric conditions. The 18.6-year mean of all high-tide elevations is called mean high water (MHW), the 18.6-year mean of all low-tide elevations is called mean low water (MLW), and the 18.6-year mean of all sea-level elevations is called mean sea level (MSL). There are also means for spring high (MHWS) and spring low tides

Coasts, Coastlines, Shores, and Shorelines, Fig. 2 Hypothetical cross section of a shore showing the classification into backshore and foreshore based on topographic features and water levels

(MLWS), as well as neap high (MHWN) and neap low tides (MLWN). These temporally averaged elevations can also be affixed to associated sheared lines (shorelines) between the ocean and the land. To standardize the use of the term shoreline, it is appropriate to affix it to a specific water level, such as mean high-water shoreline (MHW-shoreline), mean sea-level shoreline (MSL-shoreline), mean low-water shoreline (MLW-shoreline).

Atmospheric conditions also have influences above and beyond the gravitational effects described above. Low-pressure systems can elevate water surfaces, winds can pile water on the shore, and waves may runup on a shore above the still-water elevation of the sea. Daily effects of these atmospheric events on water level result in “actual” water levels that are generally different from predicted values.

The slope of the shore profile also has a very important influence on the how far water levels may shift up the shore surface (Fig. 3). Typically, beaches have slopes between 1 and 3°. At gentle slopes, a 1 m rise in water level related to atmospheric conditions may cause the position of a shoreline to shift landward 188 m. This type of shift can be accomplished without any addition or removal of sediment from the shore (“morphostatics”).

Breaking waves are other processes that influence the position of the wet and dry boundary at a shore (Fig. 3b). As waves break at the toe of the shore, the wave-bores surge forward and strike the beachface. The momentum of the water continues forward and the water (called swash) rushes up the beach profile. Swash often rises 1.5 times the wave height above the still water level (SWL). Since wave climate is spatially and temporally variable, then the average elevation of the swash limit is seasonally different, and different along dissimilar areas of the coast. If an average wave height can be estimated for a region’s wave climate, then a mean swash elevation (MSE) can be estimated for any reach of shore. Similarly, a standardized mean swash shoreline would represent the wet/dry boundary of a shore influenced by its associated wave climate. Thus, on any given day the predicted water levels from gravitational tides are rarely accurate because of the variability in atmospheric phenomena. Field and remote observations of shoreline locations are temporally very specific, and the sheared line between the water and the land is generally not related to a specific standardized elevation.

Geologists and oceanographers do not agree on the placement of shorelines on maps and charts. Since geologists are

Coasts, Coastlines, Shores, and Shorelines, Fig. 3

(a) Cross-sectional sketch of a steeply and gently sloping shore. Given a constant vertical tidal range, the horizontal spreads of water across a gently sloping surface is considerably greater than across a steeply sloping surface. (b) After a wave breaks, the rush of water up the beachface (swash) shifts the location of an observed shoreline landward of the projected still-water-shoreline

primarily interested in depicting land surfaces, the high-water shoreline is generally used as the datum for these maps. Topographic quadrangles published by the US Geological Survey (USGS) place the shoreline at mean high water or at the North American Geodetic Datum (NAVD 29) which is generally very close to mean high water. On the other hand, the National Oceanographic and Atmospheric Administration (NOAA) publishes charts that are primarily for navigational purposes. Oceanographic cartographers consider any surface that is subaerially exposed as land whether it is always exposed or only exposed periodically by tidal inundation. The datum (and shoreline) for NOAA charts is positioned at MLW or mean lowest low water. It is for this reason that the intertidal zones on maps and charts are often not surveyed, and are simply described as flats and marsh without elevation data.

Shoreline Dynamics

Short- and long-term processes govern the positions of shorelines. A change in shore form created by shifting volumes of sediment is called morphodynamics. The processes of sediment erosion, transportation, and deposition along the shore often result in shifts in shoreline positions. Magnitudes of shoreline shift are expressed as linear units (e.g., meters or feet) where negative values often indicate landward retreat and positive values indicate seaward shifts. During short-term events, shorelines at different elevations on the beachface respond differently. During storms, material is often eroded from the upper part of the shore and deposited at the toe of the shore. As a result, the MHW-shoreline may shift landward, while MLW-shoreline shifts seaward. In this case, the directions of shift for the MHW and MLW-shoreline are opposite, while the MSL-shoreline may have remained stationary. Thus, the use of only one shoreline is insufficient to study the short-term morphodynamic events. However, over long periods, the shift direction of the upper, middle, and lower

shorelines tend to be the same, and a specific shoreline might be reliable for studying long-term changes.

Rates of shoreline shift may be used to describe how fast a shoreline is shifting. The rates of shoreline shift are expressed in linear units per time (meter/year or feet/year). During short-term events, consistency in the use of a specific shoreline is important since the upper and lower parts of the beachface respond differently to storms. During long-term intervals (annual to decadal), the gross shift rate and the net shift rates may be significantly different since the directions of long-term shift are bipolar. For example, if a shoreline retreated landward 5 m in 5 years and then advanced 5 m seaward for the next 5 years, the gross shift rate would be 1.0 m/year, while the net shift rate would be 0.0 m/year. At very long-term rates (centuries to millennium), shoreline shift rates are impacted by the chronic Holocene rate of sea-level rise.

Shores and Shore Prisms

Since a shore is a strip of land associated with a shoreline, a standardized subdivision of a shore is logically defined by the series of mean shorelines described above. The mean shorelines are associated with specific elevations on the shore surface. These elevations are associated with a horizontal planar surface that extends under the land surface (Fig. 4). The material above each planar surface represents the sand prism of a specific portion of the shore. For example, the mean low-water shore (MLW-shore) is the prism of sand located above the mean low water elevation (and between the MLW-shoreline and the landward limit of the backshore). Each of the standardized shorelines has an associated standardized shore. The mean sea level shore (MSL-shore) is the prism of sediment located above the elevation of mean sea level. The mean high-water shore (MHW-shore) is the prism of sediment located above the elevation of mean high water. The mean swash elevation shore (MSE-shore) is the prism of dry sand

Coasts, Coastlines, Shores, and Shorelines, Fig. 4 A block-diagram sketch illustrating the relationships among four “mean” water levels, four mean shorelines, and four shore prisms located above each horizon.

located above the mean limit of swash runup on the shore (Fig. 3b). These shore prisms are valuable units for describing specific changes to the shore. Since each prism is composed of a specific volume of material, then removal of a portion of that volume is by “geological” definition called erosion. The addition of a volume of material by definition is called accretion. Note that erosion and accretion requires the addition or removal of a mass or volume of material.

Shore Accounting

Beach profiles are often made perpendicular to the shoreline to study beach processes. The area between the profile and MLW elevation represents a two-dimensional section of the shore. When combined with a one-dimensional length of shoreline, the resultant prism is a three-dimensional section of shore. Thus, pairs of profiles can be used to estimate the volume of sand stored in reaches of shore. Standardized elevations can also be used to determine the volume of material stored in each of the standardized sections of a shore prism. Thus, an accounting of material can be made for each shore zone that provides information on the erosional and accretional characteristics of the shore. Using the technique of profile comparisons along a stretch of shoreline, rate scales can be devised to normalize the change rate per unit length of shoreline and/or period of time (Oertel et al. 1989).

During storms, material is often eroded from the upper portions of the shore and deposited on the low portions of the shore. The process may result in no net gain to the total shore volume although there was a shift in the location of a large amount of material. An accounting of material in the total MLW-shore might illustrate a stable volume suggesting a passive condition. An accounting of material in the MSE-shore would illustrate erosion, while the accounting of material in toe of the shore between MLW and MSL would show accretion. The dynamic nature of the shore can only be realized by an accounting of material in vertically stratified zones. The shore zones (related to mean water levels) provide a valuable framework for relating patterns of shore-volume change and shoreline shift.

Common Misusage

The most common misuse of shoreline is the expression “shoreline erosion” and “shoreline erosion rate.” A shoreline is a one-dimensional construct on a planar surface. It has length but no width or depth. In this case, it is a line that denotes the boundary between a solid (land) and a fluid (water). By definition erosion is the removal of a mass or volume of material. Since, the line is one-dimensional, it has no volume or mass. Eroding the line would be equivalent to erasing the boundary between land and water. In strict scientific terminology the expressions “shoreline erosion” or

“shoreline erosion rate” are nonsensical. Shorelines shift landward or seaward across a surface, but do not erode. The landward shift of a shoreline should be described as shoreline retreat, while the seaward shift of a shoreline is called shoreline advance. A rise or fall in water level (that does not require the processes of erosion or accretion) may induce shoreline shifts, or it may be a response to erosion or accretion of material from parts of the shore. The advance or retreat of a shoreline is expressed in linear units (meters or feet). The terms erosion and erosion rates must apply to the change in the size of a volume or mass of material.

Since erosion is the removal of a mass or volume of material, shore erosion is used to describe the removal of material from all or part of a section of shore. It is a three-dimensional process requiring a reduction in the size of the shore sediment prism. An increase in the size of a shore sediment prism is described as shore accretion. A decrease in the size of a shore sediment prism is described as shore erosion. Erosion and accretion are expressed in units of volume (generally cubic meters or cubic feet). Erosion and accretion rates are as expressed in volume units per time (e.g., cubic meters/year of cubic feet/year).

The gross amount of material transported in the littoral system is often used as a surrogate for shore erosion. This is another incorrect use of terminology. Material transported in the littoral zone is described as littoral drift. The rate of littoral drift is generally expressed in units of volumetric units per time (e.g., cubic meters of sand per year). This is a transport rate, and is not a substitute for an erosion rate. The rate is a gross amount of material being transported in the littoral zone. Since, erosion is a measure of the removal of material (not transport) the two may not be equivalent. For example, the gross amount of sediment entrained in a littoral current (in a section of shore) may be constant at about 15,000 m³ in a month. During the transport of this material, the littoral current can remove and add material to the shore. If the amount removed is equal to the amount added then there is no change to the shore sediment prism. However, if the rate of littoral drift is not constant along adjacent sections of shore, then erosion or accretion may result. Gradients in the rates of littoral drift along a section of shoreline may be used to imply erosion or accretion rates. That is, if more material is being transported into a section of shore than is being transported out of a section of shore, then the rate of accretion will be the net difference between the input and output rates.

The use of remotely sensed data is a popular tool for studying rates of shoreline shift. By comparing shoreline locations at two different times, the amount of shift can be estimated over a specific duration. The resultant rates are often used to predict rates of change. Typically, the shoreline is defined by the wet/dry boundary found on an image. Since, each image represents a “snap shot” in time and not one of the standardized elevations (described above),

then it is difficult to discern whether any shift was caused by changes in the volume of sediment at the shore (morphodynamics), or changes in water level (morphostatics). Changes in water levels could be a response to different combinations of tidal stage, barometric pressure changes, waves runup, and wind stresses. On a flat beach, these forces could combine to produce several meters of water-level rise resulting in over 200 m of shoreline shift (without a change to the position of a MSL-shoreline or any change in the size of the shore sand prism). This is the $\pm$ error that should be attached to shoreline shift measurements at low-profile beaches. Therefore, it is very difficult to use remotely sensed data to analyze rate of shoreline change without vertical control.

Cohesive Sediment Transport

Parmeshwar L. Shrestha¹ and Alan F. Blumberg²

¹Exponent, Inc., Irvine, CA, USA

²Jupiter, Hoboken, NJ, USA

Definition

The transport of fine-grained sediment comprised primarily of clay- and silt-sized particles, mixed with organic matter and, sometimes, quantities of very fine sand.

Introduction

Sediments are a major component of the suspended load and bed load in coastal water bodies (estuaries, lagoons, river mouths, tidal flats, etc.). These sediments can be classified as cohesive and noncohesive. Cohesive sediments are comprised primarily of clay-sized ($<2\ \mu\text{m}$) and silt-sized ($<62.5\ \mu\text{m}$) particles, mixed with organic matter and, sometimes, quantities of very fine sand. Noncohesive sediments are primarily sand and gravel-sized material ($>62.5\ \mu\text{m}$). The underlying property that distinguishes cohesive sediments from noncohesive sediments is that they are cohesive in nature, exhibit poroelastic or viscoelastic rheological characteristics and non-Newtonian behavior when in a fluid-like state (Mehta 2002). Cohesion is the predominance of attractive forces over repulsive forces, such that particles in close proximity can bind together to form flocs (aggregates). This can be attributed to the presence of clay and colloidal particles with surface physico-chemical forces that are significant. A clay fraction greater than about 10% is generally sufficient for the sediment to exhibit cohesive properties (van Rijn 1993).

Cohesive sediments are transported to coastal waters from alluvial and marine sources. Alluvial sediments are derived from various terrestrial processes and human activities and are comprised of both cohesive and noncohesive materials. The fine sediment load is often termed as wash load in river mechanics. The coarser sediments are deposited in the upper reaches of the river/estuary while the fine sediment fractions are carried further downstream into the estuarine/coastal waters where salinity enhances aggregation, forming flocs that possess higher settling velocities. These aggregates then deposit in areas where velocities are sufficiently small. Marine sediments originate from the nearshore bottom. They are first suspended into the water column by the action of waves and currents and are subsequently transported upstream by the net upstream near-bed flow to zones of low velocities where they eventually deposit. Understanding cohesive sediment transport thus requires knowledge of both sediment behavior and water movement.

Because of the affinity of pollutants to cohesive sediments as a result of adsorption, cohesive sediment transport plays an important role in characterizing the transport and fate of pollutants (e.g., heavy metals, radionuclides, pesticides, and nutrients) input to coastal waters. These pollutants originate from various land-use and marine activities (e.g., urbanization, deforestation, industrialization, mining, agricultural practices, hydrosystem construction works, and dredging/disposal activities) posing a potential threat to receiving waters. Ways to mitigate critical water quality problems are receiving the concentrated attention of environmental engineers, biologists, and ecologists. As a precursor to assessing the impact of pollutants input to a water body, a precise understanding of cohesive sediment dynamics is first necessary.

Dynamics

Cohesive sediments in coastal waters come under the influence of various complex processes. In addition to the transport processes of advection and dispersion in the water column, the principal processes influencing cohesive sediment dynamics are aggregation, settling, deposition, consolidation, and resuspension. These mechanisms are not only dependent on the inherent physico-chemical characteristics of the sediment but also on their interaction with the flow field. It is this interdependence that makes the problem of cohesive sediment transport so complex.

Aggregation

Aggregation refers to the formation of flocs comprised of primary sediment particles. The process of aggregation results from destabilization and collision. When the double layer around each sediment particle is compressed by divalent ions, the particles are destabilized and van der Waals attractive forces predominate, creating a condition conducive to aggregation. Collision occurs as a result of three primary mechanisms: Brownian motion, internal shear, and differential settling. Brownian motion occurs when the sediment particles are bombarded by fluid particles moving in random motion resulting from thermal gradients. Internal shear is due to the presence of velocity gradients in the suspending medium. Differential settling is caused by larger aggregates colliding with smaller aggregates. Brownian motion is responsible for aggregation in stationary or quasi-stationary waters forming aggregates that are weakly bonded. Internal shear predominates in dynamic aquatic systems, and the aggregates produced are more dense and durable. Differential settling is important during near-slack periods where concentrations are high. The resulting aggregates are weak and have low density. Aggregation transfers mass through the particle size spectrum toward large-sized aggregates that can be characterized by their higher porosity, increased irregularity and fragility, and higher settling rate (Krone 1963). Aggregation is influenced by sodium adsorption ratio, pH, salinity, sediment size, shape, gradation, density, turbulence, temperature, and the efficiency of collision between particles.

Settling and Deposition

The settling velocity of cohesive sediments is dependent upon the aggregation process, the suspended sediment concentration, and the ionic concentration of the suspending medium. From laboratory experiments of San Francisco Bay sediments, Krone (1962) noted that the settling velocity is independent of the suspended sediment concentrations at low concentrations ($0.1\text{--}0.3\text{ kg m}^{-3}$); with increasing concentration ($1\text{--}10\text{ kg m}^{-3}$), the settling velocity increases with concentration; and at high concentrations ($>10\text{ kg m}^{-3}$), the settling velocity decreases with increasing concentration

and hindered settling occurs. Fluid mud is associated with a lutocline (i.e., strong vertical concentration gradients) when sediment concentrations exceed 10 kg m^{-3} (McAnally et al. 2007). Reported values of settling velocity in estuarine and coastal waters range from 10^{-7} to 10^{-3} m s^{-1} (Mehta et al. 1989).

As the aggregates settle toward the bed, the near-bed turbulence controls whether the particles bond with particles on the bed or are broken up and reentrained into the water column. The stochastic nature of the near-bed turbulence is characterized by a “probability of deposition,” which is defined as the probability that particles reaching the bed actually stick to the bed (Krone 1962). This is conveniently expressed as a function of the bed shear stress and a critical shear stress for deposition. The critical shear stress is a function of the type of sediment in suspension and is generally determined from laboratory flume studies. If the critical shear stress for deposition is equal to or less than the bed shear stress, then deposition will cease provided the sediment has uniform properties (Mehta et al. 1989). The deposition rate is thus a function of the aggregate settling velocity, near-bed concentration, and the probability of deposition.

Consolidation

Once the sediment aggregates reach the bed, the flocculated structure breaks down and the aggregates will move close together. The sediments then consolidate under their own weight when particle-to-particle contact is made. The effective stress (i.e., the difference between the total hydrostatic pressure and the pore water pressure) of the soil increases with the release of pore-water pressure. The void ratio of the bed decreases with depth of sediment (i.e., the density and shear strength both increase with depth). Consideration of the consolidation of cohesive sediment beds is crucial for determining whether the bed is susceptible to erosion and how much material can be eroded. The shear strength of consolidated sediments has been estimated from empirical relationships between shear strength and dry density. Experimental results indicate that the shear strength increases with an increase in the clay content, organic matter, salinity, sodium adsorption ratio, and cation exchange capacity. The shear strength decreases with an increase in temperature, pH-value, and the sand concentration in the sediment bed.

Resuspension

Sediment resuspension depends upon the bed shear stress induced by the flow and the resistance of the bed to erosion. In coastal waters, bed shear stresses are due to the combined effect of waves and currents. These shear stresses can be quite large compared to shear stresses due to currents alone. The resistance to erosion depends upon the sediment type and mineralogy, pore and eroding fluid concentrations, the time history of deposition (i.e., whether the sediments are recently

deposited, partially consolidated, or part of a more dense bed), and chemical and biological processes. To account for the multiple-dependence between the above factors and their spatial variability, investigators have relied on laboratory and field experiments to assimilate and analyze sediment cores from various locations. The results of these studies have indicated the need to obtain system-specific data if accurate predictions of erosion are to be realized. The nature of the deposit (i.e., the bed properties) is generally characterized by a critical shear stress for erosion. Investigations on sediment erosion have indicated that when the bed shear stress at the sediment-water interface is greater than the critical shear stress of the surface in contact, then the material will erode. The amount of material that can erode is described as a function of the stress in excess of the critical shear stress.

There are two primary modes of erosion, namely mass erosion and surface erosion. Mass erosion refers to the resuspension *en masse* of sediments when the bed shear stress exceeds the critical shear strength of the bed at some depth below the sediment-water interface. Clumps of sediment are eroded. This erosion mechanism occurs when the flow is rapidly accelerating as in zones of strong tidal currents and under storm conditions. Surface erosion, on the other hand, occurs at low to moderate values of the excess shear stress where currents are low to moderate (Mehta et al. 1989). Surface bed sediments are eroded particle by particle until the bed shear stress is less than the critical shear stress for resuspension. The amount of material that can erode from the bed is limited to a finite amount. Laboratory experiments (Parchure and Mehta 1985; Tsai and Lick 1987) and field studies (Amos et al. 1992) have revealed that only a finite amount of sediment can be resuspended from a cohesive sediment bed exposed to a constant shear stress as a result of the increase in shear strength with depth of sediment.

Mathematical Modeling

To effectively assess the impact of sediment input to coastal waters, it is necessary to predict their spatial and temporal distributions in the water column and in the sediment substrate. In order to do this, it is imperative to consider the interaction between sediment transport processes and the flow field. The advent of sophisticated mathematical models coupled with inexpensive computing power has spearheaded major advances in developing simulation models. These models now strive to incorporate more complex sediment processes into tractable computational techniques. Since the accuracy of cohesive sediment transport predictions is contingent upon the accuracy of the flow field, an understanding of the hydrodynamic circulation processes is essential. In lieu of this, models for hydrodynamics and waves are generally

coupled to a sediment transport model so that the various models operate within the same computational framework, in conjunction with one another, with output from one serving as input to another.

The simplest model for cohesive sediment transport is based on zero-dimensional modeling (e.g., Krone 1985). These models are based on the sediment conservation equation, which represents the mass balance between sediment inflows, outflows, and storage (i.e., sediment deposition). The spatial variability of the sediment properties is ignored. Other models of cohesive sediment transport range from simple one-dimensional to sophisticated three-dimensional models. Some of the available models are described in Martin and McCutcheon (1998). The governing equation is based on the mass conservation principle in one-, two-, or three-dimensions, with boundary conditions of no-sediment flux at the free surface, and net erosional or depositional flux at the sediment-water interface. Odd and Owen (1972) used a two-layered one-dimensional model to simulate cohesive sediment transport in the Thames Estuary. Other one-dimensional models (e.g., Lin et al. 1983) do not describe the near-bed concentrations, which are required for determination of deposition rates. Two-dimensional models may be depth-averaged or laterally averaged. The assumption is that concentrations are well-mixed over the depth or in the lateral direction. Depth-averaged models (Ariathurai and Krone 1976; Onishi 1981; Cole and Miles 1983; Lick et al. 1994; Shrestha 1996; Shrestha and Orlob 1996) compute the sediment deposition rates from mean sediment concentrations averaged over the vertical. Laterally averaged models (Ariathurai et al. 1977; Onishi and Wise 1982) describe the distribution of sediment concentrations in the longitudinal and vertical directions. Quasi-three-dimensional models account for the vertical distribution of sediments using approximations (e.g., calculates the vertical concentration profile based on the vertical velocity distribution) (Lou et al. 2000). The current state of the art is to utilize three-dimensional finite difference or finite element models for sediment transport (Hayter and Pakala 1989; Sheng 1991; Onishi et al. 1993; Shrestha et al. 2000). These models are suitable for applications to systems where the three-dimensionality of the flow, the salinity and temperature structure, and the associated suspended sediment distribution are important.

Sediment processes embedded in the model generally include aggregation, deposition, consolidation, and resuspension of sediments. In addition to the flow field, model inputs include bed properties (i.e., bed type, grain-size distribution, dry density, and sediment resuspension characteristics), fixed and/or time-varying sediment loading from various sources, and sediment settling parameters. Sediment aggregation is generally embedded in the settling velocity formulation and is described as a function of the sediment concentration. In most models, sediment consolidation is

accounted for by discretizing the bed into a vertically segmented bed model (Shrestha et al. 2000), where the sediment layers depend upon the time after deposition. Each layer is assigned a certain thickness, density, and a critical shear stress for erosion based on laboratory or field estimates of consolidation. The assumption is that a recently deposited bed is more susceptible to erosion than an aged bed. Alternatively, consolidation is directly simulated using a consolidation algorithm in the numerical model. The resuspension from the bed is based not only on the excess shear stress but also on the age of layer. Output from the sediment transport model includes the spatial and temporal distribution of suspended sediment concentrations, the mass of sediment eroded or deposited, and subsequent change in bed elevations. Model performance is generally assessed through model-data comparison of suspended sediment concentrations and sedimentation rates. Sensitivity of the model input parameters is also assessed. Experience has shown that sediment-loading rates need to be estimated correctly if realistic predictions are to be realized.

The hydrodynamic model is essentially the driver for the sediment transport model. It provides the necessary transport information. Martin and McCutcheon (1998) review a variety of hydrodynamic models ranging from one-dimensional to three-dimensional. The dimensionality of the model is selected based on the intended use of the model. The governing equations include the continuity, momentum, and constituent (i.e., temperature and salinity) transport equations, with an equation of state relating density to temperature and salinity. Inputs to the hydrodynamic model include hydrographical (steady-state and/or time-varying flow rates from rivers and nonpoint land-based runoffs), astronomical (tides), meteorological (winds and heat fluxes), and internal density gradients (temperature and salinity distributions). Hydrodynamic models should possess the capability to predict different time scale events, ranging from semidiurnal tide scale, diurnal scale, meteorological scale (few days), spring and neap tidal scale (15 days), in addition to monthly and seasonal time scales. Model output includes water surface elevations, currents, horizontal and vertical diffusivities, and distributions of temperature and salinity. The predictive capabilities of the model are assessed via extensive comparisons with data, and a confidence is established that the model realistically reproduces the predominant flow dynamics. As an example of a particular three-dimensional model application and its comparison with field data, the reader is referred to Blumberg et al. (1999).

Bed shear stresses due to currents and waves are crucial for calculating sediment resuspension and deposition fluxes. Wind waves are high frequency short waves of periods 3–20 s. These waves not only increase mass and momentum fluxes, but also increase bed shear stresses by inducing large velocities near the bottom of the water column. The

development of wind waves in coastal waters is based on a balance between wind energy input, wave energy, and wave energy dissipation. The wave climate is predicted from a wave model such as SWAN (Holthuijsen et al. 1993), HISWA (Booij and Holthuijsen 1995), the Great Lakes Environmental Research Laboratory (GLERL) wave model (Schwab et al. 1984), SMB (USACE 1984), WAVD (Resio and Perrie 1989), or ACES (Leenknecht et al. 1992). Inputs to the wave model are bathymetric depths and a two-dimensional, time-dependent surface wind field. Linear wave theory is used to translate the wave height and period into a near-bed peak orbital velocity and peak orbital amplitude. A wave-current model can be used to calculate the bed shear velocity. The bed shear stress is then calculated as the product of the fluid density and the square of the shear velocity.

One of the critical features in the application of the above models is the type and quality of data available for creating model inputs and for calibration and validation of the model. In this regard, data assimilation and analyses represent a core component of any modeling effort. Because of the widespread use of such modeling tools, sediment transport studies are often supplemented by field sampling and monitoring programs. For many studies involving the fate and transport of sediment-associated pollutants, hydrodynamic, wave, and sediment transport computations are linked to one or more water quality models.

Summary

This entry emphasizes the key mechanisms influencing cohesive sediment transport in coastal waters. These processes are complex because of the interaction between the physico-chemical properties of the sediment and flow parameters. Mathematical modeling provides a tool to assess the impact of the predominant processes on the transport and fate of sediments discharged to coastal water bodies.

Conservation of Coastal Sites

Vincent May

Department of Conservation Sciences, Bournemouth University, Poole, Dorset, UK

Conservation of coastal resources has been practiced throughout human history as communities have endeavored to manage the food, water, and other resources of the coast in ways which ensure that each season or year will bring at least comparable bounty from the sea and the land. Protection of coastal sites in the historic past usually meant protection of areas to be used for elite recreation or as locations where coastal resources were to be conserved. Only in recent centuries, however, have communities begun to take specific action to conserve coastal sites for their natural flora and fauna. This has meant that some areas of coastal land and water have been designated as more important for conservation than others. This may have led to distortions in the behavior of coastal ecosystems which are just as important as the distortions which conservation is intended to prevent.

What does “conservation” mean? Usually, it means management in ways which protect the inherent natural and human features and processes of an area. Conservation is often confused with “preservation,” but natural features

change. Change is normal, but it is usually a means by which sites retain their resilience.

There are many different types of coastal sites which are conserved, including archaeological, biological, cultural, geological, geomorphological, and zoological sites. There is also a wide variety of approaches to their identification, designation, and protection (Table 1).

Conservation for Biological Reasons

Ehrenfeld (1976) argued that protection of ecosystems was usually justified by two purposes: scientific and human. Typically, these include research and education, the need to protect genetic information, and as parts of the worldwide and interconnected pattern of ecosystems. Often, however, they

Conservation of Coastal Sites, Table 1 Typology of coastal conservation sites

Level of designation	Features of importance for designation	Exemplar categories	Exemplar sites
Global	Having features of ecological, biological, geological, cultural, archaeological significance at international level	World Heritage Site	Great Barrier Reef (Australia)
		Biosphere Reserve	Danube Delta (Rumania)
		Ramsar Site	Karavasta Lagoon (Albania)
Regional	Habitats of regional significance sites of importance for migrating birds	European SACs	Chesil and the Fleet (UK)
		European SPAs	Wadden See (NL, D, and DK)
National	Key habitats or species	NNRs	Studland (UK)
		Biological Reserve	Isla del Caño (Costa Rica)
		National Wildlife Refuge	Kodiak (USA)
	Protection of fauna and flora with extensive recreational activities	National Parks	Fuji-Hakone-Izu (Japan)
	Protection of fauna and flora with limited recreational activities protection of marine areas	National Monument	Fort Jefferson (USA)
		Marine Parks	Oshimoto (Japan)
		Marine Sanctuary	Farallon Islands (USA)
		MPA	Milieuzone Noordzee (NL)
		Marine Life Conservation District	Waikiki (USA)
	Protection of sensitive estuarine areas	National Estuarine Research Reserve	South Slough (Oregon, USA)
	Protection of site of scientific importance (geological or biological)	SSSI	Dungeness (UK)
		Site	Anse du Gris-Nez (France)
	Recreational site with ecological significance	National Recreation Area	Oregon Dunes (USA)
	Protection of archaeological, anthropological, or historic site	Area of Archaeological Importance (AAI)	Hengistbury Head (UK)
		Anthropological Reserve	Cota Brus (Costa Rica)
		National Historic Site	San Juan Island (USA)
Local	Protection of locally important habitats or species	Local Nature Reserve (LNR)	Lundy Island (UK)
		Ecological Reserve	Tomales Bay (USA)
	Protection of fauna and flora and provision for recreational activities	State Park	Humboldt Lagoons (USA)
	Local protection of marine habitats with extensive recreational activities	Municipal Marine Park	Balicasag Island (Philippines)
		State Seashore	Del Norte (USA)

have been protected because of the perceived importance of particular species. Usually, these are rare and, commonly, higher plants and animals. Conservation was often a response to particular lobby or pressure groups, sometimes even individuals, whose concern about losses of species and habitats led them to establish groups to provide protection to pressure governments into protecting vulnerable species. This was particularly the approach in nineteenth century North America and Europe. Today, the responsibility lies more with government bodies or conservation nongovernmental organizations (NGOs).

Conservation for Geological or Geomorphological Reasons

Geological and Geological and geomorphological sites are usually protected so that stratotypes, fossil assemblages, or structures can be observed and studied or so that specific important features are preserved and protected. The coast is a particularly good location for the observation and investigation of geological features because erosion constantly exposes new strata and because large sections can be observed without excavation. In many countries, the coast provides an accessible location for earth sciences research and education. Sites may also be important because they demonstrate the processes which mold the landscape both now and in the past. Geological sites commonly fall into two groups: “process” sites and sites which display features of geological significance. The British Geological Conservation Review which describes all designated geological and geomorphological sites of national and international importance in Great Britain refers to “process” and “integrity” sites (Table 2). Most fossil locations or stratotypes are integrity sites. At Dungeness, for example, the ridge sequence provides

a time sequence which is an integral part of recent coastline history. If it disappears that part of the history goes with it, hence it is an “integrity” site. In contrast, chalk cliffs of the Seven Sisters exemplify well the processes which occur at the coast and so this is predominantly a “process” site.

Archaeological and Historical Sites

Archaeological and historical sites include major buildings and structures located at the coast as well as sites where artifacts have been identified and excavated. Some sites are now well removed from their original coastal location by the effects of emergence, whereas others have been submerged. In shallow coastal waters, there are often very important submarine archaeological sites associated with wrecks, especially in the more active sea lanes. Some archaeological sites are at risk of disappearance as erosion cuts into them. Unless the site has considerable architectural or historical importance, erosional sites are usually not protected.

Conservation Legislation

Although the purpose of conservation laws is usually the same, that is, the protection of features or processes of high scientific or cultural value, the detailed legislation depends upon the legal framework of each nation or state. France, the United States, the United Kingdom, and Japan each have well-developed systems of conservation legislation which lay down specific procedures for the identification, designation, and management responsibility for scientifically important sites. These include coastal sites. The way in which management takes place also depends upon local tradition

Conservation of Coastal Sites, Table 2 Selected geomorphological coastal conservation sites

	Dungeness	Chesil beach and the fleet	Seven Sisters and Beachy Head	North Norfolk coast
Feature	Cusate shingle foreland	Shingle tombolo and lagoon	Chalk cliffs	Barrier beaches and spits
Key geomorphological importance	Shingle ridges in sequence from c 5,500	Large coastal fringing tombolo	Rapidly retreating	Barrier islands
	Years BP	Sediment grading	Chalk cliffs	Complex spits and
Archaeological importance	Reclamation from		Intertidal platforms	Reclaves
	Roman period to present		Cliff-top Iron Age settlements	Reclamation from mediaeval times
Biological importance	Holly (<i>Ilex aquifolium</i>) wood invertebrates	Little terns (<i>Sterna albifrons</i>) intertidal and subtidal organisms	Rock-boring organisms intertidal flora and fauna	Salt marshes

and legislation. Thus in Britain, coastal conservation is carried out both by statutory bodies such as English Nature (a government body) and by NGOs such as the National Trust and the Royal Society for the Protection of Birds (RSPB). In addition, smaller local bodies such as Wildlife Trusts also own or lease land so that they can conserve and manage areas in which rare or endangered habitats or species occur. However, the statutory bodies often are advisory organizations rather than owners of the sites. Site management depends upon the landowner or occupier of the site. This means that there may be many different organizations involved on conservation of coastal sites within short distances of each other. Their conservation policies and practices may conflict.

In many countries, there is little or no tradition of nongovernmental conservation bodies practicing coastal conservation and so responsibilities lie with government. Thus in France, the government sponsored body, the Conservatoire de l'Espace Littoral et des Rivages Lacustres (CELRL) was established to make coastal lands more accessible at the same time as protecting landscapes and properties of national importance. Modeled in part on the UK's National Trust, it is a governmental body rather than a nongovernmental membership body such as the National Trust. In some locations, First Peoples have traditionally regarded coastal lands as sacrosanct, but have no tradition of legislation to protect these lands. As a result, there are conflicts in conservation practice between traditional views of the value of coastal sites and their legal protection. Examples include the conflicts between European-based legislation and traditional approaches of the Maori in New Zealand. Legislation derived from British law conflicts with traditional law.

There may also be differences between local, national, or international legislation. Thus in the United States, both federal and state legislatures can define sites of coastal conservation and in Europe, the system of Directives which are mandatory on all member states may supplement or even override national conservation practices. The European Union's Birds (European Commission 1979) and Habitats (European Commission 1997) Directives have established Europe-wide networks of sites including many at the coast. These are known as Special Protection Areas (SPAs) and Special Areas of Conservation (SACs). In Britain, the seaward boundary of coastal sites such as National Nature Reserves (NNRs) and Sites of Special Scientific Interest (SSSIs) established under the national legislation lies at Low Water Mark, but the boundaries of SACs and SPAs can extend to the territorial limit. There is a very wide range of types and levels of conservation designations worldwide which includes World Heritage Sites, Biosphere Reserves, and Ramsar Sites designated at international level, National Parks, and Marine Sanctuaries at national level and local nature reserves (Table 1).

Conservation Measures in Different Countries

In Europe, there are considerable differences in the history of coastal conservation, usually as a result of the relative importance of government and nongovernmental involvement and action at the coast. Furthermore, there has been considerable conservation action in the past decade as a result of initiatives by the European Community.

France has the longest established nature conservation legislation in Europe. Protection of sites is the responsibility of the Ministère des Affaires Culturelles, with advice provided by the Commission Supérieure des Sites, Perspectives et Paysages and the Commissions Départementales des Monuments Naturels et des Sites. Decisions at local level must be approved by the national Commission Supérieure. The designation of sites followed the Laws of May 2, 1930 and July 10, 1976, which identified the following criteria for classification of sites as nature reserves:

1. The preservation of animal and plant species and habitats which are either in danger of extinction in all or part of the national territory or have outstanding characteristics;
2. The restoration of animal or plant populations or habitats;
3. The conservation of botanical gardens and arboreta forming reserves for plant species which are rare, unusual, or nearing extinction;
4. Preservation of biotopes and outstanding geological, geomorphological, or speleological features;
5. Preservation or establishment of staging points on the great migration routes;
6. Scientific and technical studies necessary for the development of human knowledge;
7. Preservation of sites of particular interest for studies of the evolution of life and the activities of mankind.

This approach is reflected within the European Union Directives on Birds and Habitats both of which include important coastal areas.

The largest of the French coastal nature reserves is the Camargue (13,171 ha) on the Rhone delta. In contrast, when it was designated as a Site in 1930, Port Cros, a small island off the coast of Provence, had an area of only 140 ha. The initial designation was based on landscape protection, as more was known about the newly protected site, especially its flora and fauna, the significance of the surrounding seas was acknowledged. The site was extended in 1963 to include the surrounding sea, and became the first Marine Protected Area in the Mediterranean. The inclusion of the surrounding sea recognized the importance of such species as Neptune Grass (*Posidonia oceanica*) and Grouper (*Epinephelus marginatus*). This example typifies the development of coastal conservation as sites are first identified to protect a particular species or habitat and then expanded to account for

improved understanding of the site and its surroundings. However, conservation can be very slow in practice. For example, at Port Cros the conservation objectives have been restricted by the impact of over half a million visitors annually and local resistance to conservation measures, such as a ban on angling from the shore which restricts traditional coastline activities.

The 62 coastal Départements may designate for protection the habitats of protected species that are threatened and acquire land financed through the Taxe Départementale des Espaces Naturels Sensibles (TDENS: Departmental Tax for Sensitive Natural Areas), often in association with the CELRL (Meur-Férec 1997). The Law of May 2, 1930 allows for designation of either Site Classé (classified site) or Site Inscrit (listed site) for sites of special natural and built importance and has been used extensively in the protection of coastal sites (Meur-Férec 1997). The 1986 Loi Littoral (Coastal Law) provided a statutory framework which recognized the economic, social, and heritage importance of the coast and the unique nature of the coastal zone (Cicin-Sain and Knecht 1998). This provided a context for individual sites, including, for example, a setback zone of 100 m wide for the whole coast, in which development is prohibited. Marine areas can be declared protected under the 1968 Law of Maritime Hunting, essentially to protect wildfowl! In many countries with long-established traditions of hunting, conservation of these species has often meant controlled management of habitats. Although there are some strongly held objections to game conservation, it is important to emphasize that without these conservation measures many sites which are valued today for their biodiversity would not exist. The 1960 Loi Relative à la Création de Parcs Nationaux (Law for the Creation of National Parks) includes Marine Protected Areas (MPAs) by allowing the terrestrial parks to extend into the maritime region (IUCN 1994). European Union (EU) regulations and directives further supplement the national policies. Under the Birds (1979) and Habitats (1992) Directives, 133 sites have been proposed for inclusion within the European Community-wide Natura 2000 network of sites.

Two government bodies also have a role in French coastal conservation. The most important is the CELRL established in 1975. It is a public body charged with acquiring coastal and lakeside land, maintaining its ecological character and allowing public access to its sites (Cicin-Sain and Knecht 1998; European Union for Coastal Conservation 1995). Once purchased, the land is managed by the CELRL on behalf of the state in perpetuity. However, any acquisition has to take account of the area development plans and prior consultation with the Départements and Communes. This is because the day-to-day management and costs of an acquired site are handed back to the commune(s) or relevant landowner after purchase (EUCC 1995). It currently owns over

49,000 ha along 650 km of coastline (Meur-Férec 1997), including the D-Day beaches in Normandy and the Domaine de Certes at Arcachon. The Office National des Forêts (ONF, the National Forestry Office) manages 100,000 ha along 500 km of coastline, mainly forested dunes, such as the Landes. It works with the CELRL and other related administrative bodies to produce management plans for the forests. In the coastal region, ONF's work is more social and ecological than its predominantly economic role on the inland forests (Favennec 2000). In particular, it is responsible for dune stabilization work, where it often has to balance the needs of conservation with tourism and public access. Thus at Pointe d'Arçay it has implemented a management plan devised with public participation and at Cap-Ferrat has successfully reintroduced marram grass (*Ammophila arenaria*) to the dunes.

Coastal conservation in Britain started, as so often there, with voluntary bodies such as the National Trust and the Royal Society for the Protection of Birds. Previously, conservation measures were largely in the hands of individual landowners or the Crown and were mainly concerned with management of game or food resources. In 1949, the National Parks and Access to the Countryside Act established the Nature Conservancy as well as the national parks. The Nature Conservancy and its successors (three country agencies: English Nature, the Countryside Council for Wales (CCW), and Scottish Natural Heritage) were concerned with the geological and biological importance of sites for research and education. National Nature Reserves were established together with areas designated as SSSIs. The Royal Commission on Historical Monuments describes and studies sites of historical and archaeological importance, including many coastal sites. The Ancient Monuments and Archaeological Areas Act 1979 provides for the protection of archaeological sites and monuments and does appear to extend into territorial waters, although there is no record of designations at sea. These Acts and bodies are generally empowered only to deal with sites above Low Water Mark. However, the European Directive on Habitats specifies Marine SACs and so specific attention now has to be given to subtidal and submarine sites around the UK coastline. The Directive has force for the coastal waters of all European member states, although the detailed legislation is made at national level.

Submarine and marine sites are dealt with under different legislation. The Merchant Shipping Act 1995 deals with wrecks and salvage, requiring reporting of finds and the Protection of Wrecks Act 1973 provides some protection for important or dangerous wrecks or their sites. War graves may be designated under the Protection of Military Remains Act 1986: diving on and interference with a designated war grave is an offence. International agreement to protect graves in civilian shipwrecks in international waters was given effect in the Merchant Shipping and Maritime Security Act 1997.

The biological sites were reviewed in detail by Ratcliffe (1977) and coastal geomorphological and geological sites have been the subject of a major national review (the Geological Conservation Review [GCR]) which has identified almost 100 coastal geomorphological sites (May and Hansom 2003), plus a number of coastal landslide sites and several hundred geological sites. The Nature Conservation Review (Ratcliffe 1977) described three stages in site classification:

1. Recording the features of each site to describe the range of ecosystem variation in terms of environmental and biological characteristics;
2. Comparing the quality of these sites; and
3. Choosing a series of nationally important sites.

The criteria used in both assessment and selection of key sites were

1. Size of the site;
2. Diversity;
3. Rarity of the species;
4. Naturalness, that is, areas which have been modified least by humans in so far as they are identifiable;
5. Fragility: habitats which are highly fragmented, rapidly decreasing in number and/or area, difficult to recreate or threatened with extinction;
6. Typicalness;
7. The recorded history of the site;
8. The position within an ecological or geographical unit;
9. The potential natural value of a site;
10. The intrinsic appeal of a site.

The Nature Conservation Review identified 140 coastal SSSIs with a mean area of 1,957 ha; 8 sites exceeded 10,000 ha in area. At the same time, France had 131 sites of average size 456 ha. 78% French sites were less than 100 ha in area, whereas 42% British sites exceeded 1,000 ha. For coastal geomorphological sites, criteria have included not only the specific importance of the site, but also the processes affecting particular rock-types or structures. As a result, sites with comparable geological conditions have been selected with micro- and meso-tidal ranges and different wave climates. There are 100 geomorphological sites which include large shingle structures such as Dungeness, major landslides such as the west Dorset coast, major dunes such as Morrich More on the east coast of Scotland, and world-renowned features such as Lulworth Cove and the stack of the Old Man of Hoy.

Although their coastal conservation is based upon different traditions both in coastal use and in their laws, France and Great Britain show very well how complex the legislation and administration of coastal conservation has become. Countries with shorter experience have been able to adopt different, and

sometimes more efficient, approaches. Furthermore, the European Community has adopted its own framework for conservation in order to establish a community-wide network of related sites.

Funding of coastal conservation is similarly complex and depends upon receiving levels of funding which allow management to be carried out. The British model relies heavily upon voluntary support, membership, industrial support, bequests, and fundraising (Fig. 1).

Typically, the largest voluntary bodies have strong marketing and sales departments. Funding from national and local government is limited in amount and has to be competed for. Such funding is often restricted in time. In contrast, in France or the United States, for example, conservation is predominantly funded by official sources, with the national and local governments largely responsible for both funding and operation of the conservation sites. The manner and volume of funding may change with a change of government. Thus, although the arrangements shown in Fig. 1 for government funding applied in 2000, a reorganization of government departments following a General Election in June 2001 altered some of the responsibilities. In Britain, local authorities have only limited inputs into conservation funding, whereas the French Départements have considerable fiscal and legal tools at their disposal. They may, for example, acquire land financed through the TDENS (Departmental Tax on Sensitive Sites). Often these acquisitions are made in conjunction with the CELRL, and all the 62 coastal Départements have used these powers to purchase land (Meur-Férec 1997). The day-to-day management and costs of an acquired site are handed back to the commune(s) or relevant landowner after purchase (EUCC 1995). The majority of funding comes from the state but legacies and public/corporate donations also help with the acquisition and management of sites. Apart from the State, the CELRL is France's second largest landowner but interestingly, its budget is one-fifth of the National Trust's, a British NGO that operates a similar protection by acquisition policy (Meur-Férec 1997).

At the time of the French Law of 1976, many European countries had hardly established relevant legislation. Greece, for example, had very good legislation concerning its archaeological sites, but was only just beginning to identify natural sites (May and Schwartz 1981). Similarly, Norway's Nature Conservation Act of 1970 initiated action to preserve and protect plants, animals, and birds and areas of importance to nature conservation which, within a decade, established a network of 13 national parks, almost 200 nature reserves and over 200 locations which were of natural scientific importance. Many are at the coast. In contrast, Poland created its first National Park inland at Bialowieza in 1932 and there are now eight protected coastal areas including two National Parks, the Slowinski (founded 1967: present area 18,619 ha) to the west of Gdansk and the Wolinski Park near the German

Conservation of Coastal Sites, Fig. 1 An example of funding for conservation of coastal sites. Key: *DCMS* Department of Culture, Media and Sport, *DETR* Department of the Environment, Transport and the

Regions, *CAP* Common Agricultural Policy, *CFP* Common Fisheries Policy, *RSPB* Royal Society for the Protection of Birds

border (founded 1960: present area 10,937 ha). The Polish Environmental Protection Bill 1992 provides for three “levels” of designation: Strict (usually no admission to the public: 22% of sites), Partial (where management controls are flexible: 59%), and Landscape Protection (where so-called “soft laws” apply: 19%). This recognizes that although some areas must have strict controls over access in order to protect sensitive areas and species other areas are more resilient and more appropriate for human activities such as

recreation. National ecological policy requires that 30% of Polish territory (including coastline) should eventually be designated as “protected,” 22% of the area had been designated by 1997. Coastal conservation in Poland is thus a national responsibility rather than a regional or local one. This is a typical pattern of many countries which have relatively recently begun to conserve coastal sites. The strength of national legislation often, but not always, ensures that designation and appropriate funding occur.

Spain combines national and local approaches to conservation. It has a long history of environmental legislation but the first specific conservation (in its modern sense) legislation was the 1975 Law on *Espacios Naturales Protegidos* (ENPs: Protected Natural Areas). This proposed four categories of protected area: national park, natural park, natural area of national importance or interest, and reserve of scientific interest. Other later laws have established over 25 different categories (WCMC 1992). The national body responsible for administration of protected areas is the Instituto Nacional para la Conservación de la Naturaleza (ICONA: National Institute for the Conservation of Nature). Set up in 1971, its functions include the encouragement of renewable resource use and maintenance of ecological balance; the creation and administration of national parks and sites of national interest; and the development and exploitation of inland fishing and hunting assets. With decentralization of the government in 1978, responsibility for many conservation issues passed to Spain's 17 autonomous communities (*Comunidades Autónomas*) which are responsible inside territorial waters for the protection of marine and coastal areas from human activities. The 1989 Law on the Conservation of Natural Areas, Flora, and Wildlife strengthened this responsibility further. The protection of coastal areas is covered by the *Ley de Costas* (the Shore Act: July 28, 1988) based on the French model (Barragan 1997). The Shore Act requires protection of the sea up to 100 m offshore and restricts the number of road and pedestrian routes to the coast. It also defines a zone extending 500 m inland which affects land and urban planning as well as prohibiting the disposal of waste in this area (WCMC 1992). As in France, this provides a national framework within which conservation of coastal sites may take place. Laws concerning sustainable use and conservation of living marine resources have been adapted from the Directives of the European Community since these require member states to bring them into force.

The Waddensee: An Example of International Cooperation in Coastal Conservation

International cooperation is sometimes essential if the integrity of coastal ecosystems is to be protected, one of the best examples being the Waddensee in the southern North Sea. The Wadden Sea is the largest unbroken stretch of intertidal mudflats in the world and is extremely productive. With a biomass considered equivalent to rainforests, it is recognized as one of the most important wetland areas in the world. Up to 30 km wide, the Waddensee extends from the northeast Netherlands through Germany to the southwest coast of Denmark and includes low barrier islands, tidal flats, salt marshes, sand dunes, woodland and grassland, and low barrier. It is a very important breeding and overwintering area for a high proportion of the coastal birds of the North Sea. It is also, however, an area of reclamation, oil and gas

extraction, commercial fisheries, and resort development. The three countries have cooperated in its conservation since 1978 using a joint memorandum which provides the basis for planning, conservation, and management of the area. In 1997, they adopted the Waddensee Plan, which was developed by involving all stakeholders and has as its focus the conservation, restoration, and development of all the region's ecological features. The interests of the local population, traditional uses of the area, and habitat conservation must be balanced with the other needs of sustainable management and preservation. Seven principles have been used to bring about regulation of activities that threaten its environment and to provide for active intervention as necessary, namely (de Jong et al. 1999):

- Careful decision making – based on using the best available information
- Avoidance – avoiding potentially damaging activities
- Precautionary principle – avoiding damaging activities, even if there is insufficient scientific evidence to link them to specific impacts
- Translocation – moving damaging activities to areas where they will cause a reduced impact
- Compensation – using compensatory measures to offset unavoidably damaging activities
- Restoration – restoring areas which have been damaged
- Best available techniques and best environmental practice should be adopted.

The most important lessons are that international cooperation is essential for the conservation of some vital sites, that there must be agreed targets and procedures, and that local people must be involved especially when their traditional activities form part of the ecosystem as a whole.

In contrast, although some of the less-developed countries of eastern Europe have taken few steps to conserve coastal sites, the role of international conventions such as the Ramsar Convention on Wetlands of International Importance, 1971 and international cooperation in species protection, especially for marine turtles, have had an impact. In some respects, the significance of tourism as an economic driver for conservation has been overlooked although tourism provides a very strong incentive for conservation and sustainable activities. In Albania, for example, the isolation and centralization of the economy and society over the last 50 years affected community behavior as local communities were excluded from the planning process and decision making about natural resources upon which they depended. Not surprisingly, they consider that conservation and habitat protection have ignored their needs and imposed restrictions without providing benefits.

Albania designated its first Ramsar site in 1994 (RAMSAR 1996, 2001), comprising the Karavasta Lagoon and adjacent Divjaka National Park. In the 1960s, much of the

wetland was drained for agriculture, affecting the biodiversity of the lagoon, as well as the surrounding catchment, the Divjaka forest and hills, and its human communities. The total area of the site is 20,000 ha, made up of native forest of *Pinus pinea*, a species unique to the Albanian coast, and the lagoon itself (5,800 ha) which is a brackish water system connected to the sea by artificially maintained channels. The freshwater input to the lagoon comes from runoff from the surrounding agricultural land and Divjaka hills. Karavasta Lagoon has the only coastal breeding population of the Dalmatian pelican (*Pelecanus crispus*) along the Adriatic and Ionian coasts, supporting up to 5% (700–1,000 individuals) of the total world population. A significant proportion of the European breeding populations of Little Tern (*Sterna albifrons*) and Collared Pratincole (*Glareola pratincola*) use the Karavasta wetlands during migration, as well as large numbers of waterfowl, gulls, and terns, including the globally threatened pygmy cormorant, and white-headed duck.

Despite its designation as a Ramsar site, the lagoon has been seriously threatened by inappropriate tourism development which has often damaged fragile coastal habitats upon which its wildlife depend. Pollution and overfishing have added to the stresses on the lagoonal ecosystem. Some of the reclaimed wetlands are affected by high levels of salinity and so are of limited agricultural value. The area is state-owned and managed jointly by the General Directorates of Forestry and Fisheries (both part of the Ministry of Food and Agriculture). In practice, management depends upon a small number of rangers with limited experience of specialized wetland management, training, or equipment. Future strategies include improved planning and management of the lagoon to both protect the ecosystem and its biodiversity (including the pelicans) and derive economic benefits for local communities. A management plan for the site was prepared with international, technical, and financial cooperation through the European Union's PHARE program (PHARE 1996). The Karavasta Lagoon is an example of where there is a need to involve local communities in biodiversity conservation activities and demonstrate their benefits. Karavasta exemplifies the problem that conservation of coastal sites depends upon management of the human systems which decide how the area will be sustained.

The United States of America

A very wide range of different designations are used in the United States, many within the framework of the National Parks legislation. They range from areas such as National Parks where they exist for both preservation of natural and cultural features and for recreation to specialized research areas, such as the National Estuarine Research Areas that are devoted to research (Table 1). There is a wide network of sites at state and federal level, but the initial establishment

of important sites depended upon very strong individual lobbying of the federal government and the role of individuals such as John Muir in getting presidential support. Coastal sites were generally established later than inland sites.

The origins and variety of the coastal sites is well illustrated by the coastline north of San Francisco (Table 3). From very humble beginnings, some sites such as the Farallones Islands have grown to major national coastal and marine sites. Designations overlap so that within the Point Reyes National Seashore, for example, there are not only marine and terrestrial reserves, but also historic ranches within the Philip Burton Wilderness Area (California Coastal Commission 1987). State, county, and private parks and reserves also occur. However, there are few sites owned or managed by private organizations. Estuaries, such as San Francisco Bay, have been extensively reclaimed with the accompanying loss of wetland habitat. This is a worldwide feature of coasts and serious concerns about the loss of biodiversity and productivity have been expressed within the United States for many decades. Since 1850, reclamation has cut off over half of the bay's tidal marshes and open water from tidal action and 95% of the original wetland habitat has been lost (California Coastal Commission 1987). Nevertheless, San Francisco Bay contains 90% of the coastal wetlands of California and remains a major part of the Pacific coast bird migration route. Responsibility for the wetlands is divided between the Bay Conservation and Development Commission (tidal wetlands) and the US Corps of Engineers (nontidal wetlands), a division which does not recognize the natural hydrological links between them.

In many less-developed countries, funding for conservation is largely provided through tourism receipts, or by international aid programs and funding from international bodies such as the World Wide Fund (WWF) for Nature. Pressure for conservation action and designation typically comes from pressure groups. The implications of conservation action and site or species protection are not always well considered. For example, a ban on turtle fishing along the Pacific coast of Mexico had immediate impacts upon the local economy and knock-on effects to other parts of the coastal ecosystem. The contrast between the approach in many less-developed, but biologically rich, regions is well demonstrated by two examples, Costa Rica and the Mexican state of Oaxaca.

Costa Rica

The Central American country of Costa Rica has a well-established system of designation and protection of its ecosystems and biodiversity, including coastal sites. As the examples in Table 4 show, these sites include very large areas of land and sea which protect different habitats and some small sites which are most

Conservation of Coastal Sites, Table 3 Coastal conservation in the United States – California examples

Site	Designation	Responsible authority	Key features	Area (ha)
Southeast Farallon Island	Bird Reservation (1909)	Presidential order following pressure initiated by Director of California Academy of Sciences	Major seabird nesting site protection to prevent large-scale damage to birdlife by commercial egg companies	26
Southeast Farallon Island	Farallon Reserve (1911)	Re-designation. First statutory protection	Public concern over wildlife endemic Farallon weed major seabird nesting site	26
Farallon Islands	National Wildlife Refuge (1972)	US Fish and Wildlife Service and Point Reyes Bird Observatory	300,000 birds in 12 species nest annually. Over 350 species of birds migrate via the islands World's largest nesting populations of ashy storm petrels, Brandt's cormorants and western gulls northernmost breeding site for northern elephant seals	40
Farallon Islands and surrounding waters (up to 6 nautical miles offshore between bodega head and rocky point and waters within 12 nm of the islands)	Gulf of the Farallones National Marine Sanctuary (1982)	Gulf of the Farallones National Marine Sanctuary (Federal Agency)	Diverse productive marine ecosystem based on upwelling	
Point Reyes National Seashore	National Seashore	National Parks Service	San Andreas fault very diverse ecosystems >360 bird species recorded	Almost 29,000
Limantour Estero	Reserve (within National Seashore)	National Parks Service	Estuarine habitats: removal of all life forms prohibited without permit	202
Bodega dunes	Sonoma State Beach	State Department of Parks and Recreation	Dunes up to 50 m high	364

Marsh	Not designated	Canyon Ranch	Freshwater marsh	16

important for particular species. These sites are all nationally designated and form part of a network of sites designed to represent and preserve Costa Rica's wide biodiversity.

Mazunte: An Example of Conservation in Action

Mazunte on the Oaxacan coast of Mexico is, unlike the Waddensee, in one of the poorest areas of the world. It shows how changes in conservation policy can be accompanied by local community involvement in coastal conservation especially when this is focused upon sustainable

development. However, it also demonstrates the tenuous nature of much coastal conservation in less-developed areas.

For more than 30 years, Mazunte (the name comes from a Nahuatl word meaning "please lay eggs") was dependent upon turtle catching and canning. Most people in the village were either fishermen or worked in the cannery. A Presidential decree in 1990 banned all turtle fishing following significant lobbying by WWF. The immediate effect was to remove the community's main source of income, as the local community express it, throwing "our

people into misery!" Protection of one species (turtles) was enacted at the cost of another. Some local people abandoned the area and moved inland to occupy land within the coastal dry forest, the associated clearance having potentially damaging effects on coastal lagoons as sedimentation increased. The turtle populations were recognized as being under stress from poaching, predators, and disease. The Mexican Center for Marine Turtle Research (CMT) was established in late 1991, using the buildings of the former Society of Industrial Fisheries of Oaxaca, and now has a unique role as the only center which studies seven out of the eight species of marine turtle. In addition, a community-based project known as Ecosolar and a Reserva Ecologica Campesina were established. Within Mazunte itself, a small ecotourism project was based upon sustainable principles and designed to provide accommodation for mainly foreign visitors to the area. Further to the south, the large-scale resort development

of Huatulco had a major impact on the unusual dry coastal forest and the coastal beaches and lagoons.

The attempts to conserve not only the turtles and their nesting beaches but also to build a sustainable community have not proved easy, for both human and natural intervention have conspired to threaten the coastal ecosystem. In the aftermath of an uprising in 1994 in Chiapas, there was considerable local unrest which affected Huatulco in August 1996. This had a serious impact on the turtle ecology because, when police were sent to the resort, up to 200 poachers went to local beaches where Olive Ridley turtles were arriving to lay eggs. It is estimated that up to one million eggs were lost and large numbers of turtles killed. In October 1997, the area was struck by Hurricane Pauline which caused serious damage to both the CMT and other buildings but also devastated the nesting beaches. 806,000 nests were affected, with half all the nests on Escobilla beach, four million eggs and up to ten million

hatchlings lost. Nevertheless, the turtles continue to nest on these beaches. The CMT carries out detailed studies of turtle behavior and ecology both in the Center and on the beaches and the growth of the resort of Huatulco has brought increasing numbers of visitors to Mazunte. The concept of the Reserva Ecologica Campesina is unusual in that it links deliberately the human community with the coastal ecosystem. Knowledge which once served the commercial interest of turtle canning has been harnessed to develop an approach to sustainable development which has shown itself to be very resilient to significant human and natural disruption. The financial support for the CMT is very small, less than US\$70,000 annually, and receipts from the ecotourism project are also small. Conservation here is not about conservation of a site, so much as conservation of a whole ecosystem (including its human occupants). For many communities, this will be the future for coastal conservation for it is firmly based in local knowledge, the needs of the local community, and their own initiatives.

Conclusion

The conservation of coastal sites takes many different approaches, often with detailed legal and administrative frameworks for designation and protection, but also in relatively informal ways with the involvement of NGOs and private ownership. In some countries, it has only been through the effective active involvement of individuals and NGOs that conservation has been put into practice. The example of Mazunte is a modern, but more community-based, expression of people's wish to protect and conserve features of their environment which they value which was expressed in different words and actions by the founders of the National Trust or John Muir and the Sierra Club. Once established, such initial routes to coastal conservation need the support of the national and international communities to make sure that they are truly sustainable and not threatened by external political, economic, and social pressures. Although coastal conservation is well established in practice, there are nevertheless enormous threats to many sites from urbanization, resource extraction, tourism, pollution, large-scale coastal projects such as barrages, and reclamation and neglect. Sea-level change and climate change also threaten many sites, although their history shows that most sites are resilient to change provided that human activities allow natural resilience.

Note

The International Union for the Conservation of Nature (IUCN) World Conservation Monitoring Centre (WCMC) in

Cambridge, England, is the most important source of information regarding protected sites.

Continental Shelves

A. W. Niedoroda
URS Corporation, Tallahassee, FL, USA

Introduction

Continental shelves are the submarine platforms that surround continents. They are found in the open ocean and in many of the coastal seas. Similar features surround subcontinents, such as Greenland, and many oceanic islands. These features exhibit a wide variety of physical dimensions and characteristic relief. Most commonly, they are relatively flat with slopes varying between $1:10^2$ and $1:10^4$. Depths at the seaward edges of continental shelves are generally on the order of 80–100 m, although there are places where depths are less than 50 m or greater than 200 m. Beyond the shelf edge is the continental slope, which is typically inclined on the order of $1:10^2$ to $1:10^3$ and frequently has much more local relief than the continental shelf.

General Morphology

In most places the continental shelf has distinct subzones. Although the nomenclature is not standardized, it is customary to divide the zone between the surf zone and the shelf edge into four major reaches. These are: (1) the *shoreface*, (2) the *inner shelf*, (3) the *mid-shelf*, and (4) the *outer shelf*. On most open-ocean shelves the shoreface, with a slope on the order of $1:10^2$, occurs between depths of 5–25 m. It has a convex upward slope which is steeper at its top. This zone is also occasionally called the shore-rise and is considered by some to be part of the inner continental shelf. The inner continental shelf is usually taken to extend seaward to the point that the coastline no longer significantly influences wind-driven circulation. This distance is strongly affected by the strength and duration of the wind at any given time. It is usually on the order of 5–15 km wide.

The outer-shelf and mid-shelf environments are also defined by their dynamic processes. The outer shelf is where there is significant interaction between deep ocean and shelf circulation patterns. On the mid-shelf, circulation responds to the restricted depths but is not dominated by interaction with ocean currents or near-shore circulation. Because continental shelves have widths in the range of 10^0 – 10^2 km, the characteristics of these subzones are quite variable.

Large-Scale Characteristics

Continental shelves can also be divided according to their modes of origin, dominant processes, and geographic

locations. In most places around the world where the coastline has been tectonically stable the shelves are broad and of low relief. Often these are simply submerged continuations of adjacent coastal plains, which themselves are extensive. Conversely, where continental margins are overriding adjacent seafloor as a result of continental drift, the shelves tend to be narrow and steep. These are often adjacent to coastal mountain ranges. The inner part of continental shelves at low latitudes is a common site for coral reefs and other forms of carbonate platforms. Shelves around the Antarctic continent, the Arctic Ocean, and certain other high-latitude places are strongly influenced by processes related to sea ice. On some high-latitude shelves, permafrost can be found a few tens of meters below the sea bottom. This attests to the combined effects of severe cold and the relatively recent rise of sea level.

The sedimentary environments and deposits on continental shelves are quite varied. In some places rock platforms extend beneath the shelves and sediments are distributed as thin sheets or in patches. These conditions are encountered where the underlying rock is relatively young (such as in volcanic areas), where the supplying of sediments is limited (e.g., west Florida Shelf), or where recently drowned shelves had been scoured by glaciers. Deposits greater than 10^3 m occur where prolific sources of sediments exist (Mississippi Delta foreshore). In some places, the predictable patterns of sandy nearshore sediments grading to silt and mud near the shelf edge are found. However, there are few general rules. In some locations muddy sediments occur all the way from the shore to the shelf edge. Elsewhere, the entire shelf is covered with sandy sediments, possibly with local patches of silt and mud.

Many broad continental shelves, especially those in stable tectonic areas, are sediment-starved today. In these areas the coastline is characterized by broad estuaries. Sediments, transported in river bedload accumulate at the estuary head. The sandy adjacent continental shelves are the result of reworking of previous deposits. In many cases, the previous deposits represent ancient shore processes from times of lower sea level. At the opposite extreme, there are cases where river deltas extend across the modern shelves so that the seaward face blends into the continental slope. The delta of the Mississippi River is an especially good example.

Shelf Features

Although continental shelves tend to have broad areas of low relief, there are many morphological features that characterize this environment. These can be conveniently divided between erosional features, depositional features, and modified relic features. The most common erosive features originated during periods of low sea level when rivers extended entirely across to the shelf edge. Because there were several

major sea-level excursions during the Pleistocene, there have been several extended periods where river and river canyon development have been promoted. In some cases, there are no remnants of these ancient river courses evident in the bathymetric shape of the bottom. However, subbottom profiles show channels now filled with sand. In other cases, quite obvious river valleys extend across the continental shelves to submarine canyons that extend down the continental slope. In some places drowned river terraces and bluffs can be found.

Depositional features dynamically coupled to present sedimentary processes and features representing the reworking of previous deposits are both found. The dynamic sedimentary features include sand ridges, sand waves, and a host of lesser bedforms. *Sand ridges* are long features with characteristic heights of 1–10 m, spacings (i.e., wavelengths) of 10^3 m and lengths up to several kilometers. These may be either shoreface-connected or freestanding sets on the lower shoreface and mid-shelf regions. The *shoreface-connected sand ridges* tend to be oriented obliquely to the shore with the acute angle pointing in the direction of dominant longshore sediment transport (Duane et al. 1972; Swift and Field 1981; Caballeria et al. 2001; Calvete et al. 2001). These features are generally thought to migrate slowly down the coast. The freestanding sand ridges occur in sets in a wide range of shelf environments (Nemeth et al. 2001). They may occur on the tops of shallow sand banks close to the shore. They are also common features in mid-shelf environments. These too are prone to slow migration, although shelf sand ridges in some locations occupy remarkably stable locations.

Sand waves are geometrically similar features that are smaller than sand ridges. They have heights on the order of a few meters, are spaced at distances (i.e., wavelengths) on the order of 10^2 m, and extend 10^2 – 10^3 m in length (Nemeth et al. 2001). These may appear in extensive fields over broad sandy areas or as secondary features on the crests of sand waves and sand banks. Recent research has shown that sand waves are dynamically stable bottom forms that are brought about by shelf currents through a complex feedback mechanism that includes systematic changes in the structure of turbulence. These large bed forms are stable as either fixed or migrating features.

Shoreface-connected and open-shelf sand ridges as well as sand waves tend to occur in parallel sets with quasi-regular spacing. Many other forms of bottom relief are less regular in shape and spacing. These include sand ribbons and irregular bars. The reasons for these features are generally poorly understood, although many represent the results of reworking of sand deposited during an epoch of lower sea level.

In order to explain many of the morphological features that have been developed on continental shelves through the reworking of previous features, it is necessary to briefly

consider sea-level history. Many of the shelf features developed as a result of the migration of the shore across the shelf since the last glacial maximum approximately 18,000 years ago. Worldwide sea level rose approximately 110 m, but the rate was not uniform over this period. The rate of sea-level rise was greatest between 12,000 and 7000 yr. BP. However, throughout the entire recent period the rate of rise has varied within shorter intervals (1500–4000 yr.). More details are provided in Donoghue et al. (2003). Variations in the rate of sea-level rise have caused the shore migration rate to change considerably. At times of slow rise, or rise-reversal, the shore position remains nearly constant. Shore features become well-established and considerable deposits of sand develop. Subsequent episodes of rapid sea-level rise can cause overstepping of these features. They are reworked, but not entirely obliterated. As the availability of dense bathymetric data sets has increased it has become easier to detect and explain these features.

The concept that barrier islands retreat landward in the face of rising sea level is well established. This is brought about by processes that carry sand over and behind the islands while the seaward face erodes. Features formed off the seaward side of these islands can be preserved if their initial volumes are large. In several locations along the northern Gulf of Mexico coast, the huge volumes of sand in ebb tide delta are too great to be disbursed as they are drowned by the ongoing rise of sea level. This results in leaving elongated sand bodies stretching many kilometers onto the shelf. In most cases these features correlate with a position of present estuaries, although they may not be aligned with present tidal inlets.

Because the rate of sea-level rise since the last glacial maximum has been unsteady, with millennia-scale fluctuations, the migration of shore features has also been episodic. In areas where there are plentiful supplies of sand, barrier island complexes extending from the shoreface, across the island, and including the washover deposits in the lagoon, have tended to form during periods when the rate of sea-level change is low. Again, these huge sand deposits resist obliteration when they are drowned during episodes of rapidly rising sea level. Much of the upper portion of these *shore-complexes* is reworked and lost. However, the general morphology can be distinguished where there are sufficiently detailed bathymetric data. In these places subbottom profiles reveal dipping beds representing lower shoreface and back bay deposits (Donoghue et al. 2003).

Many ancient coastal river deltas have also been large enough to avoid being obliterated during periods of rapid sea-level rise. These are now located on the continental shelf. The shelf edge is where many of these are found because the last sea low-stand was below this elevation. Additionally, some major sand shoals on the continental shelf originated as deltas during the transgressive phase of the past sea-level cycle.

Subaqueous deltas are also found on continental shelves. These are sediment clinoforms with nearly flat tops and seaward-dipping foreset beds. However, unlike coastline deltas, these features formed with their tops on the order of 10 m below sea level. Examples of these can be found off the mouth of the Amazon River (Nittrouer and DeMaster 1996), and in the Italian Adriatic (Trincardi et al. 1996). Unlike the drowned deltas described above, these subaqueous deltas are actively forming at the present time.

There are many extensive morphological features, consisting largely of sand, which occur as isolated *banks* or *shoal complexes*. Although many of these have complex histories and origins, there are others that are members of feature classes with common explanations. Swift (1973) has introduced the term *massif* in conjunction with these features. Generally, a *massif* is a very large volume of sand that has originated near the coastline and has subsequently been drowned and reworked due to sea-level rise. *Shoal retreat massifs* originated from the complex of sand shoals that form across the mouth of many broad estuaries. The ancestral location of these estuaries may be far out on the present shelf. As sea level rose, both the estuary mouth and the related shoals migrated landward leaving huge volumes of sand behind. Although these are now being reworked by the action of waves and currents, the very size of these deposits protect them against obliteration. However, there must be many cases where smaller features have not been so persistent.

Cape shoal retreat massifs have also been described (Swift et al. 1972, 1973). These are thought to originate at the apex of coastline capes in barrier island systems that existed far out on the shelf. The system was subsequently drowned by sea-level rise and traces of the barrier islands obliterated. However, the large collection of sand at the point where the littoral transport systems converged produced a linear shoal mass that extends far onto the present shelf. These are often still connected to capes in barrier island systems.

Shoal retreat and cape retreat massifs, along with many other sand banks that originated from the reworking of previous massive sand deposits, often provided the sites for extensive sand ridge and sand wave fields. This is an excellent example of how a portion of many shelf features represents the result of ongoing processes while other aspects of the same features represent more ancient causes.

The work that resulted in this entry has been assisted by ongoing research in the ONR EuroStrataform Project (Contract Number N00014-03-C-0134).

Coral Reef Coasts

Charles R. C. Sheppard
Department of Biological Sciences, University of Warwick,
Coventry, UK

Coral reef coasts occur almost entirely between the Tropics of Cancer and Capricorn, though functional exceptions involving fossil reefs may extend beyond these limits. The reef component of a coral reef coast is constrained by the

physiological requirements of the corals themselves, which include clear, warm water, neither too fresh from river outflows (>30 ppt) nor too saline from high evaporation (<40 ppt), with a temperature range of between about $15\text{--}30^\circ\text{C}$, and not heavily sedimented. Exposure levels are rarely limiting; corals thrive from very sheltered to extremely exposed conditions.

Because reefs grow vertically to the low tide level, they provide very effective shelter to the coast, which in turn greatly affects the habitats which lie in their lee. The more closely a reef is located to the coastline, the greater the shelter will be. Extremely sheltered coasts lie behind fringing reefs with broad reef flat components, over which water always remains $<1\text{--}2$ m deep. Reef development may take place some distance offshore, in which case greater fetch and depth between reef and shore leads to higher energies impinging on the coast. In numerous cases, the series of coastline reefs may lie far offshore (east Africa, Great Barrier Reef), possibly even on a line along the edge of the continental shelf, so that coastlines are little protected, added to which the presence of the reef itself may funnel longshore water movement which may add to net coastline erosion and dynamics. In numerous locations, fringing reefs and more distant barriers of reefs, or series of patch reefs, combine to provide complex patterns.

Reefs are biogenic limestone structures, sometimes called bioherms. Thus, over time, reef development shapes the coastline itself, and the shape and morphology of the system decreasingly depends on, or even reflects, the inherited landscape form. While it is usually the case that the limestone-depositing organisms usually can only settle on preexisting hard substrates, they also may develop on unconsolidated substrate where the latter exists in sufficiently sheltered conditions. Good examples of this are found in the Red Sea, a region famous for both its general aridity and excellent fringing reefs lying close to and contiguous with the coast. Here, cores have shown layers of solid reef alternating with layers of unconsolidated sand and rubble of mainly terrestrial origin. The formation of these series comes from alternating phases of reef growth, followed by reef obliteration when heavy rains and sediment deposits carried by flash floods deposit terrestrial materials in thick blankets over the reefs. Alluvial fans develop, prograding to seaward, which then support vast areas of productive shallow water between their leading edge and the shore. Sheltered conditions then allow a new cycle of reef growth to develop on the fans. Depending on current patterns (and repeat episodes of heavy rain) these fans may then infill, extending the land to seaward until greater depth and steep slopes at the seaward edge precludes further progradation.

Uplift of reefs also affects coastline morphology. Clear examples again occur in the Red Sea (Fig. 1) where series of tectonically uplifted reefs extend inland on the coastal

plain. The Red Sea is an example of a spreading plate with current seismic uplift but, equally, substantial examples of uplifted old coral reef coastlines occur on most continents, notably east Africa and Australia.

Biological Systems

Biological systems supported along reef shores are usually rich and diverse. Apart from the productivity and biodiversity of the reefs themselves, any areas of hard substrate between the reef and shore are likely to be colonized extensively by corals. Sand accumulates along these shores from wave pumping over the reefs – mostly the sand being limestone, derived from eroding reef material, and fragments of coral and coralline algae. Soft substrates commonly dominate the shoreward coastal marine environment. If stable enough, seagrasses may thrive, themselves being a rich habitat supporting high productivity and a considerably greater biodiversity than adjacent, uncolonized sand. Once these angiosperms take root, they stabilize the habitat further.

Along the coastline itself in such areas, mangroves may dominate the intertidal habitat, particularly if estuarine or at least slightly lowered salinity conditions prevail. These forests may be extensive and grade inland into true terrestrial forests, or may be very shallow-rooted in very limited sediment (Fig. 2) and are known as “hard substrate mangroves.” Most mangrove trees have roots and shoots which trap and stabilize sediments. This can also lead to progradation of the coastline to seaward as well as laterally alongshore. The existence of the mangroves, as with seagrasses, commonly is the direct result of the shelter provided by the reef lying to seaward. Conversely, the existence of the large, shore-colonizing stands of rooted plants, traps and consolidates substantial amounts of sediments that otherwise would reach and adversely affect the reefs, which are extremely intolerant of sedimentation. Thus, complex feedback processes determine both the physical and biological nature of the coral reef coastlines, as well as their physical extent. Seaward progradation may attain a balance, depending on the extent of shallow substrate on which the reef exists and over which it may extend, but rates of progradation are fairly slow; considerably slower than may be the case, for example, where mangroves extend the land seaward near heavily sedimented estuaries in the absence of reefs.

Coral island Shores

These are a special case in which reefs themselves are the only component of the coastline. The modern component may be only a veneer on pre-Holocene reefs, or may themselves

Coral Reef Coasts, Fig. 1 (Top) A central Red Sea fringing reef, whose reef flat is at low tide level. The edge of the reef flat is seen <100 m to seaward, following which the slope dips steeply to hundreds of meters. The person is lying on a tectonically raised fossil reef whose

elevation is about 4 m. (Below) Plots of ages of reefs and their heights above sea level. (Data taken from review material in Sheppard et al. (1992), Table 1.1)

develop into thick deposits. Their shallow existence traps sediments, then limited vegetation, birds and further vegetation, in well-documented patterns of biological succession. Known as cays, keys, or islets of atolls, globally their total coastline is considerable, especially in deep oceanic regions distant from continental coasts. In these, all hard substrate is limestone, and all soft substrate is derived limestone sand. Most of the latter will undoubtedly be modern, though where hard substrate exists, outcrops of pre-Holocene material may be expected.

Typically, these coastlines have classical profiles of a low island, followed by a reef flat at low tide level, and a reef slope which dips to seaward, smoothly or in cascades. These reef slopes may be very narrow, less than 20 m wide, this distance in extreme cases being all that separates an island shore from water which rapidly attains depths of several hundred meters. More commonly, reef flats extend for upwards of 100 m, and may be dry or become extremely shallow for up to about a quarter of the tidal cycle. In exposed areas these may be bordered by an algal ridge; a construction of calcareous red

Coral Reef Coasts, Fig. 2

Fringing reef backed by “hard substrate” mangroves and, on the shallow reef flat, dark patches denote areas of rich seagrasses. The three habitats of reef, mangrove, and seagrasses are closely linked. (Location is in the Sinai peninsula and these mangroves are amongst the most northerly in the world)

Coral Reef Coasts, Fig. 3 The spur and groove structure along the seaward edge of an oceanic atoll. Formed from growth of calcareous algae (*Porolithon* spp.) it is the primary defence against erosion for the reef and the shore behind (Chagos atolls, Indian Ocean)

algae which faces the oncoming waves (Fig. 3). Usually algal spurs extend more or less regularly to seaward from the ridges for a further 100 m, dipping to 5–10 m depth. These structures have a tremendous wave-baffling role, in that their length and spacing appears to be “tuned” in such a way that incoming waves meet the outgoing swash from the preceding wave, their energies partly cancelling each other out. It appears that the very existence of many coral reef shores depends to some degree on this algal, biogenic coastline structure.

Human Habitation on Coral Reef Coastlines

Coral reef coastlines have always been populated, and because reefs and the other rich habitats along these sheltered shores are rich in food sources, notably fish protein, limitations on human numbers have commonly been due more to the availability of freshwater rather than to the supply of food (Sheppard 2000). In rainy tropical areas, human populations have been considerable for long periods of time, while in arid

locations, such as the Middle East, there usually have been far fewer – and more nomadic – people despite the richness of marine foods.

As well as the limiting effects of little or highly seasonal rainfall, the permeable nature of these fossil coral and modern coral island coastlines have long affected the amount of water which may be stored and extracted, and this also has greatly affected the ability of people to live on them. Freshwater lenses on modern coral islands are small and clearly change rapidly in size; they track the quantity of rainfall and they are clearly tidally linked, rising and falling diurnally, often with phase lags of only a very few minutes. They are thus very sensitive to over-abstraction. The available freshwater is also sensitive to increased runoff to sea which takes place following development of human habitation; here significant proportions of the land become covered with built-up areas which are impermeable, causing water to runoff rather than enter the water table. Both the latter and over-abstraction readily cause a collapse of the water table – one marked example is seen in the current sulfurous and saline nature of the water table on Malé, the very built-up and now artificially shaped capital town (and island) of the Republic of the Maldives (Fig. 4). Interestingly, it has also been suggested that where the water table seeps laterally to sea in the region of the intertidal zone in carbonate shores, chemical changes, coupled with microbiological growth, causes solidification of “beachrock” a durable form of limestone which also contributes to coast line stability (Fig. 5).

Where freshwater and biological systems are not over-stretched, human populations may continue to live. The productivity of all three major habitats (reefs, seagrasses, and mangroves) are amongst the most productive in the world (Sheppard 1995) and, in addition, offshore production in

these areas may also yield substantial additional fish such as tuna.

However, numerous factors currently combine to create unsustainable conditions which have led to numerous system collapses and abandonment of coastal villages throughout tropical Asia, Africa, and Central and South America. Pollution from sewage and industries, unsustainable methods of fishing (e.g., dynamite and DDT “bombs”), unsustainable amounts of previously sustainable types of fishing, extraction of coral reef material for building, and infilling of the shallows between reefs and shore to create more land, have all caused ecosystem collapses in coral reef coastlines and have spelled disaster for the local inhabitants. Currently, nearly two-thirds of reefs have been damaged (Bryant et al. 1998) though this figure is nearer 80% in areas such as Southeast Asia. Similarly, removal of the mangroves for timber or to clear space for unsustainable shrimp farming, and whose existence protected the seaward reefs by trapping terrestrial sediments, permits previously stabilized sediments to blanket and kill the reefs leading, eventually, to coastline erosion. Even poor agricultural practices far inland have resulted in massive movement of topsoil into these coasts via river flow, again causing mass mortality of habitats and starvation of people (Sheppard 2000). Compounding the damage is the fact that such reef-sheltered coastlines tend to be disproportionately rich in their provision of breeding, spawning, and nursery areas for marine species.

Effects of Climate Change and Sea-Level Rise

Although reefs grow vertically to the low tide level, and did so during the rapid and substantial Holocene transgression (the

Coral Reef Coasts, Fig. 4 The capital city and island of Male, Republic of Maldives; a coral reef island city. The reef flat is almost entirely infilled. A breakwater (on left) was built by Japanese aid following devastating surges and loss of land. Water abstraction has left the water table damaged, now with saline and sulfurous water

Coral Reef Coasts, Fig. 5 Beach rock formation. Where freshwater seeps into the intertidal, microbial growth leads to solidification of the fine sands. These appear to be extremely important in the creation of dipped limestone slabs in some areas (Chagos atolls, Indian Ocean)

sea-level rise of about 150 m in about 8,000 year), their ability to continue to do so under present conditions of rising sea level and temperature is not at all certain. First, sea surface temperature increases and El Niño events in recent decades have caused mass bleaching and mortality of corals. In 1998 in the Indian Ocean, for example, coral mortality in shallow reef areas exceeded 80% in many and probably most atolls, and in many patch reefs and fringing coral reefs in the Arabian Gulf, southern Red Sea and many continental shores. As of mid-2000, recovery appears poor. It is known that coral erosion continues, and since growth and erosion in a healthy reef are closely balanced (in favor of growth) net erosion may now be predicted with concomitant reduction of breakwater effect. The importance of the breakwater effect on reefs is marked, and can be seen when reefs have been removed previously by other reasons: for example, by coral “mining” on reefs around islands which have lowered the surface of the reef by 0.5 m, or from mortality of corals through disease which resulted in similar loss; in such cases the loss of the reef has led to severe erosion of the coastline, sometimes exceeding 1 m per year until a new stable point is reached. Given the attractiveness of development on “reef front” locations, infrastructure damage has often been substantial. Both of these forms of reef loss are likely to mimic the loss following recent episodes of temperature-induced mortality.

It is likewise known that coral growth and reef growth become “decoupled” as environmental conditions become increasingly severe (Sheppard et al. 1992), and that even continued coral growth does not necessarily result in continued growth of the essential hard, durable reef. Further, while it is generally understood that reef growth results in deposition

of vast quantities of carbonate, a point important in the consideration of possible carbon sinks to combat rising global CO₂ levels, in fact a rising atmospheric CO₂ level also alters water chemistry dynamics in the direction of *reducing* deposition of carbonate; estimates of a 21% reduction of carbonate deposition by 2065 have been postulated given Intergovernmental Panel on Climate Change estimates of CO₂ rise (Leclercq et al. 2000). While the latter work has primarily been directed at the question of the global carbon sink, clearly reduced carbonate deposition on reefs which protect coastlines will become increasingly important too, as the fine balance between reef accretion and erosion becomes disturbed in favor of erosion.

Thus, while healthy reefs may continue to keep pace with a rise in sea level, as has been the case before, the increasingly stressed and damaged reefs appear to be decreasingly capable of fixing CO₂, have a decreasing ability to maintain rich coral- and reef-forming (limestone-depositing) communities, and possibly even a decreased ability to maintain food production for human populations. Evidence is accumulating to show that pressures on reefs, including over-fishing, lead to changes to their ecological stable states which cause them to be dominated by different species groups, even if or when the pressure initially causing the change is removed. The replacement biotic groups may be dominated by non-calcareous species, and the trend appears to be one-way, like a ratchet rather than a wheel. If confirmed further, substantial changes to coastlines currently protected by reefs are likely to occur, the direction of the changes being characterized by increased erosion, reduced productivity, and reduced ability of these coasts to support the human populations currently living there and dependent upon them.

Coral Reef Islands

Gisèle Muller-Parker

Department of Biology, Western Washington University,
Bellingham, WA, USA

A coral reef island is composed of rocks from coral skeletons, that is, biologically formed calcium carbonate materials derived from the adjacent coral reef and raised above sea level. Coral reef island sizes range from a few square meters to many square kilometers, and they come in all shapes and proportions. Their soils consist of coral fragments, calcareous algae and other limestone detritus, varied amounts of humus, guano from sea birds, volcanic ash, and drifted pumice (Fosberg 1976).

Coral reef islands can develop only where suitable conditions sustain coral growth over time. These conditions include favorable physical factors (high temperature, high salinity, good light penetration, and low nutrients) and biological

factors (especially a supply of coral larvae) in tropical regions that provide a firm substrate in the shallow photic zone (Birkeland 1997). Coral islands are created in three ways, which are not mutually exclusive: (1) accumulation of dead coral reef rubble and sediments on top of a reef flat through wave and storm action, resulting in a low island (several meters in height) that may be ephemeral or stable; (2) emergence of a coral reef due to a drop in relative sea level; and (3) uplift of the ocean floor beneath the reef. Coral reef islands resulting from tectonic uplift of coral substrate may range from several to hundreds of meters in height.

The life span of coral reef islands is determined by the balance of erosional and depositional processes, and by sea-level rise. Coral islands drown when their corals are submerged below a critical depth for coral growth (Grigg and Epp 1989). During their existence, these nonvolcanic islands may become vegetated and support a terrestrial fauna and flora. Coral reef islands are fundamentally different from so-called “coral islands” that consist of fringing coral reefs growing on a foundation provided by an island of volcanic or continental origin. Coral reef islands may be associated with volcanic or continental land masses if they form as the result of depositional processes arising from fringing or barrier reefs. These islands may lie on barrier reefs separated by a lagoon of varying widths from high land, and their proximity to this land may result in some terrigenous sediment input to coral reef islands.

Darwin's theory of reef formation asserts that the three main reef classes, fringing, barrier, and atoll, are each different stages of development of a coral reef (Darwin 1842). Darwin did not define a coral reef island, simply referring to the islands on atolls as islets of various sizes and shapes. Dana (1872) defined “coral islands” as reefs that stand isolated in the ocean (= atolls), away from the shores of high islands and continents which harbor “coral reefs.” His definition is clearly too restrictive, although he clarified it by stating that a coral island has a lagoon in the middle instead of a mountainous island and consists of a very low ratio of habitable land to area. Other terms associated with coral islands also have different local meanings. Extremely small coral islands on atolls are called islets or cays, while others refer to small coastal islands as cays (“keys” in Florida), some of which are not derived from coral reefs. “Coral cay” defines a small low coral reef island. “High” and “low” islands are terms often applied to coral reef islands. High islands are generally not coral reef islands since most consist of volcanic or continental materials with surrounding fringing or barrier reefs. However, uplifted coral reefs may attain a height similar to some high islands. Low islands are true coral reef islands if their sedimentary origin is coral reef material.

Classification of Coral Reef Islands

Stoddart and Steers (1977) placed coral islands into seven different classes based on morphology and sediment characteristics, with vegetation used as a secondary diagnostic. Vegetation patterns depend on elevation, surface features, area, distance from sea, soil development, and human activities (Fosberg 1976). Stoddart and Steers (1977) stress that these islands do not necessarily evolve from one class to another; any change results from external influences, primarily storms. The first class includes unvegetated and vegetated sand cays, which are low-lying accumulations of coral rubble and sand deposited by wave refraction on the reef. Sand cays are generally associated with barrier reefs and patch reefs in protected areas of reefs, for example, in lagoons behind barrier reefs. They occur on reef patches in shallow, wide lagoons and assume a variety of shapes depending on sea level, wave energy, and tidal ranges (Hopley 1982). The windward margins of the cays tend to be composed of loose coarse rubble and the leeward sides accumulate sandy sediments. These terrestrial piles of coral material may eventually develop vegetation, mostly of plants from seeds deposited by birds or by ocean currents. A lagoon may form in between, with mangroves helping to stabilize the sediments (Guilcher 1988). These islands range in maximum dimension from several meters to greater than 1000 m, with a height of several meters. Unvegetated islands are lower in height and ephemeral in nature. The second class of coral island is the *motu*, which is the most common island in the Indo-Pacific. Motus have a seaward (windward) shingle ridge 3–5 m high and a leeward sandy shore and are generally vegetated. These islands occur most frequently on the exposed windward sides of atolls on the inner reef flat on Pacific atolls where sediments and rubble are deposited by strong unidirectional waves. Motus vary in number, size, and shape on a given reef or atoll. Islands in the Tuamotu atolls range from 250 to 300 per atoll, covering 30–35% of the atoll rim. Most atolls in the Marshalls, Gilberts, and Ellice groups contain more than 20 islands, while the Carolines support fewer than 10 islands per atoll (Stoddart and Steers 1977). The number of islands on an atoll depends on the number of erosional channels (“*hoa*”) cut through formerly continuous atoll rims. The vegetation on motus is strongly influenced by elevation above sea level and island size. A freshwater lens can develop on larger islands which will support a more diverse flora and fauna. The third and fourth classes of coral islands are the shingle cay and mangrove cay. The shingle cay is a storm-related event not common on coral reefs, while mangrove cays are formed by colonization of shoal areas by mangroves. Mangrove cays with a windward sand ridge form the fifth class, and low-wooded islands are the sixth class. The seventh class consists of emerged coral reefs (limestone islands). Examples of emerged coral islands include the northern

Florida Keys, the Bahamas, and Bermuda in the Atlantic ocean and Aldabra atoll in the Pacific ocean. These are often dissected into karst topography with steep and strongly undercut shores, sharp peaks, and sinkholes.

Distribution of Coral Reef Islands

Most coral reef islands occur in the Indo-Pacific region. There are over 300 atolls and extensive barrier reefs in the Pacific ocean and only 10 atolls and 2 barrier reefs in the Caribbean region (Milliman 1973). The total number of coral reef islands is unknown, and varies according to change in sea level and storm activity.

Summary

Coral reef islands occur throughout the world at tropical latitudes. They are best viewed as products of the reef and as an extension of the reef ecosystem (Heatwole 1976). Ecological studies are needed to determine the physical and biological linkages between the coral reef and its islands. Although most coral islands occur in isolated areas, human influences on the vegetation and fauna are highly evident and easily quantified. These land forms are excellent geological and ecological systems for studying interactions between marine and terrestrial ecosystems.

Coral Reefs

Scott Smithers and David Hopley

Environmental Science and Management, College of Science and Engineering, James Cook University, Townsville, QLD, Australia

Coral reefs are the largest structures built solely by plants and animals and many are clearly visible from space. Gross distribution is limited by a requirement for warm water with an average winter maximum temperature of 18 °C generally regarded as providing the poleward margin for coral reefs which are thus found only in a few areas outside the tropics. High temperatures above 30 °C may also be lethal to corals. Other requirements include good water circulation and a generally low nutrient status for ambient waters. In the open ocean where nutrient availability is very low, coral reefs exhibit a very efficient nutrient recycling, the marine equivalent of tropical rainforests. Inshore reefs can tolerate higher nutrient levels and may even respond with more rapid growth rates, though this may be countered by the skeleton laid down being more fragile. Turbid waters have a detrimental effect, limiting the penetration of light in the water column and compressing the vertical zonation of the coral reef. In clear open waters corals may grow to depths exceeding 110 m. In turbid water this may be limited to 10 m or less.

The Importance of Plants on the Reef

Many of the restrictions on coral growth are imposed not by the corals themselves but by plants. Within the endodermal tissue of the coral polyps are unicellular algae, zooxanthellae, which have a close symbiotic relationship with the coral host. The zooxanthellae not only provide some of the nutrition for the coral but also aid as important primary producers of oxygen and carbon during daylight hours through the process of photosynthesis. They are also nutrient conservators, satisfying their own requirements from the host metabolic waste which they thus assist in removing. Most importantly, they are direct promoters of inorganic growth of coral skeletons. In daylight, the algae produce more oxygen than can be used by

polyp respiration and some of the carbon dioxide produced by the respiratory process is refixed by the algae into new organic matter. As photosynthesis takes up C-12 slightly faster than C-13 the organic matter synthesized by the zooxanthellae has a relative preponderance of C-12 and a pool of carbon compounds enriched in C-13 is left behind. It is from these that the calcium carbonate skeleton is built, aided by pH variations associated with the diurnal photosynthetic process. Corals grow 2–14 times more rapidly in light as opposed to darkness and twice as fast on a sunny day as opposed to a cloudy day.

Other algae also participate in the growth and maintenance of the coral reef. Crustose coralline algae infill and cement the coral structure especially on the high energy margins of the reef where they build distinctive pavements and ridges. *Halimeda* producing delicate plates of calcium carbonate can be extremely prolific in producing sediment and, given appropriate nutrient pulsing, can build bioherms as significant as the coral reefs (as for example in the northern Great Barrier Reef, and the Makassar Straits of Indonesia). At their poleward limits competition from macro algae which can over-shade the corals, is a factor in coral reef distribution.

Coral Reef Diversity and Ecology

Coral reefs are amongst the most complex and diverse ecosystems on earth (Dubinsky 1990). A variety of marine invertebrates and plants contribute to the accumulation of the limestone which are the most massive bioconstructional features in the geological record. Symbiosis with zooxanthellae occurs not only in the corals but in other major calcifying organisms including giant clams and foraminifera which are a major producer of reef sediment. Other important calcifiers include bryozoans, sclerosponges, echinoderms, and a wide variety of molluscs. They contribute to both the reef framework and the infilling sediments. At the scale of the total reef ecosystem gross primary organic production is very high but conversely, because of the amount of recycling which occurs, net productivity may be close to zero. In contrast, calcification is the most active of any ecosystem on earth. With an estimated total area of 617,000 km² the estimated total annual production is estimated at 929 million tonnes CaCO₃.

The stony scleractinian corals are the most important of the reef biota and their diversity typifies that of many other reef-dwelling species including coral reef fish. It is currently estimated that there are about 220 coral genera and at least 1,300 species, though many are rare and/or azooxanthellate. However, there are two distinct centers of diversity. The most diverse is the Indo-Pacific centered on the south-east Asian archipelago, most significantly the Molucca and Banda Seas of eastern Indonesia. Here there are about 450 species belonging to 80 genera. Individual sites may have as many as

140 species. The other center is in the western Atlantic and is much less rich with only 20 genera and 50 species.

The reasons for this lie in the evolutionary history of the scleractinia which evolved from the earlier rugose corals of the Paleozoic (Veron 1995). The first scleractinians appeared in the middle Triassic about 250 million year ago in the western Tethys Sea approximating to southern Europe and the Mediterranean. Corals occupied a circumglobal seaway which included the Tethys Sea and the gap between the two American continents. During the Mesozoic and Tertiary, as the African, Indian, and Eurasian plates collided the Tethys Sea was closed from the west, its diverse coral fauna pushed eastwards into what is now the final relict consisting of the islands and peninsulas of south-east Asia. The Atlantic fauna was isolated first from the east, then in the Pliocene from the west as the Isthmus of Panama isolated the Atlantic from the Pacific.

The gross pattern of diversity is thus a result of geological history. However, local diversity is also dependent on the range of ecological niches available (particularly wide-ranging in south-east Asia) and the frequency of disturbances such as hurricanes, earthquakes, volcanic eruptions, or crown of thorns starfish outbreaks (Connell 1997). As coral reproduce mainly through a single annual spawning event, a medium frequency of disturbance can allow planula larval recruitment from a wide range of ecological niches because of the longevity of the larval phase which can be several weeks, allowing dispersal over hundreds of kilometers.

Rates of Growth and Accretion and the Importance of Bioerosion

The majority of corals are colonial organisms and annual extension rates for single colonies may be more than 10 cm/year for branching species and 1 cm/year for massive corals. Each year's increment consists of a wider high- and narrower low-density band which can be clearly identified by x-radiography. The high-density band is normally laid down during a period of stress imposed by either ambient environmental conditions or reproduction.

However, as the corals and other organisms are laying down calcium carbonate, many others are bioeroding the reef substrate. Some of the sediment produced may help to infill the reef framework but much is lost from the immediate vicinity of the reef. Bioeroding organisms include rock grazers in search of epilithic and endolithic blue-green algae on the reef surface, rock browsers which consume reef fabric and sediments such as parrot fish and holothurians, and a wide range of burrowers and borers. Rate of breakdown can match or exceed the rate of calcium carbonate production. For example, individual chitons can consume up to 13 cm³/year, grazing fish in Barbados reefs produce 1–2 tonnes/ha/year of

sediment, clionid boring sponges 5–10 tonnes/ha/year, and grazing echinoids up to 97 tonnes ha/year, 65% of which is lost from the reef. Boring worms such as Sipunculids and Polychaetes produce up to 20% of the porosity in the reef framework. On Rongelap atoll in the Pacific it is estimated that up to 100,000 tonnes of lagoonal sediment passes through the acid gut of grazing holothurians each year.

Coral reefs which are under stress may have bioerosion rates which exceed the current rate of limestone deposition. However, most healthy reefs are actively accreting. Rates of reef growth are commonly calculated in two different but complementary ways. Biogeochemical measurements of changes to water chemistry over a coral reef can give instantaneous calcification rates related to total reef metabolism (Kinsey 1985). Such measurements have been made worldwide and when converted to annual rates give remarkably uniform results for the different reef environments. All reefs accrete through the mix of three absolute modes of calcification:

100%	Coral cover	10 kg	CaCO ₃ ² /year
100%	Algal pavement	4 kg	CaCO ₃ ² /year
100%	Sand and rubble	1 kg	CaCO ₃ ² /year

Different zones of the reef are thus accreting at different rates. Sediment is produced from the highly active zones such as the reef front, to the less-active parts of the reef such as lagoons. Taking into consideration the density of the calcium carbonate produced (2.9 for aragonite) and the porosity of coral and reef frameworks (about 50%) these results give an upper limit of about 7–9 mm/year for reef accretion.

Using the geological record through drilling and radiocarbon dating of reef cores provides an alternative long-term method for calculating coral reef accretion rates, which are nonetheless very compatible with those from reef metabolism. The synthesized results from the Great Barrier Reef (Davies and Hopley 1983) have been reproduced from many other reef-drilling projects. Framework accretion rates ranged from 1 to 16 mm/year according to the density of the fabric (lowest for algal pavement, highest for open branching coral frameworks) though the modal rate of 7–8 mm/year is identical to that from water chemistry. Drilling has also produced rates for detrital sedimentation. In lagoons and sand aprons it is 1–4 mm/year for sand flats, 7–9 mm/year for steady trade wind accumulation and 13–18 mm/year for high-energy low-frequency events.

Coral Reefs and Sea-Level Change

Coral reef growth is highly constrained by sea level. Uppermost growth may exceed the mean low water mark in moated pools in reef flats and will die off with any fall in relative sea

level. Single tectonic events causing uplift of the land can cause mortality across an entire reef flat and in areas of constant uplift in the tropics, such as at tectonic plate margins, suites of raised reef terraces may occur to several hundreds of meters of elevation. Radiometric dating of such terraces in locations such as the Huon Peninsula in Papua New Guinea and Barbados has determined not only the rates of uplift locally but also global eustatic sea-level records.

As coral reefs have existed for such a long period, global changes in sea level have had a major impact. Global cooling during the late Tertiary and Quaternary, resulting in waxing and waning of ice sheets at the poles and in the northern hemisphere have resulted in falls in sea level of up to 150 m, exposing all extant coral reefs and removing active growth to deeper banks and slopes perhaps severely restricting the area of coral growth at the low sea level times. Fringing reefs were exposed as limestone terraces, shelf barrier reefs as chains of limestone hills, and atolls and other oceanic reefs as limestone islands. The records of sea-level change suggests that over the last million years coral reefs have been exposed for far greater a period than they have been inundated. Reef accretion has been limited to the relatively short high sea-level phases of interglacials.

During periods of exposure, which may have been as much as 100,000 year at a time, the reefs were subjected to karstic erosion processes. Indeed a series of models for the development of coral reef morphology at both the gross and detailed scale, have been hypothesized based on the karst land forms which were etched at low sea-level phases (Purdy 1974; Hopley 1982). This antecedent karst hypothesis has been used to explain the annular shape of atolls and the rim structures of barrier reefs as well as the labyrinthine morphology of many reef surfaces (Fig. 1) which have been likened to the complex ridges and enclosed depressions of tropical karst regions. Some features such as caves with speleothems, “blue holes” up to 500 m wide and 100 m deep are clearly derived from preexisting karst land forms. Blue holes on the Great Barrier Reef for example (Fig. 2) are almost certainly collapse dolines over which a veneer of 10–20 m of Holocene reef growth has occurred (Hopley 1982).

A problem with the antecedent karst hypothesis is the time available during low stands of sea level for major karst landforms to develop (see Hopley 1982, chapter 7 for discussion). Recent studies have shown that some morphology previously attributed to karst interaction has in fact been derived from reef growth in the Holocene. However, it is also possible that the growth which occurs during an interglacial high sea level may enhance that produced by erosion in the previous period of exposure.

This is then further enhanced by the patterns of erosion during the next low sea-level stand. In all probability both growth and erosion produce the complex relief of coral reef systems.

Coral Reefs, Fig. 1 Complex lagoonal relief in the large reefs of the Pompey Complex, Great Barrier Reef Australia

Coral Reefs, Fig. 2 A blue hole approximately 300 m wide and 33 m deep in Molar Reef, Great Barrier Reef, thought to have originated from a collapsed doline

In addition to the formation of karst landforms during low sea-level exposure, coral reefs also experience diagenetic changes. The original skeletal limestone is largely aragonite (corals, molluscs, *Halimeda* sclerosponges) or high Mg-calcite (crustose coralline algae) which in subaerial and vadose environments is unstable and may be replaced by a coarser crystalline low Mg-calcite (Fig. 3). Caliche crusts (Fig. 4) may form on the surface and soils can be retained over parts of the surface even after reinundation. During the subsequent high sea-level phase the older reef is recolonized and new framework deposited over the older surface. However, it remains as a clearly identifiable discontinuity termed a “solution unconformity.” Beneath the Holocene reef framework the solution unconformity formed during the last glaciation is typically 10–20 m beneath the surface. Where coral reefs have been drilled to greater depth 10 or more solution unconformities have been identified especially in atolls and shelf edge barrier reefs which suggests continuous subsidence at these sites during the period of reef accretion.

Coral Reefs, Fig. 3

Diagenetically altered *Acropora cervicornis* in the Pleistocene reef tract, Barbados. The aragonite of the original corals has largely disappeared or altered into calcite. Low Mg-calcite molds result from the more rapid replacement of encrusting coralline algae

Coral Reefs, Fig. 4 A brecciated caliche profile with numerous brown micritic stringers developed on Pleistocene reef limestones ca. 84,000 year BP on Barbados

**Reef Growth in the Holocene**

Modern coral reefs have developed entirely during the Holocene period, the majority forming a relatively thin veneer over older Pleistocene foundations which are no more than 10–20 m below modern sea level (Fig. 5). Very few radiocarbon ages greater than 9,000 year have been obtained for this Holocene veneer. Only where reefs were in deep water, such as open ocean atolls, were corals able to merely migrate to the flanks of the reef during the last glacial and thus recolonization was simple and immediate. This is also the situation for some of the midoceanic volcanic islands, which explains why the deepest and longest postglacial record comes from Tahiti. Here the postglacial reef is more than 90 m thick and basal dates older than 13,500 year have been obtained. Australia's Great Barrier Reef in contrast rises from a relatively shallow continental shelf generally less than 50 m deep. Even the lowest parts of the older Pleistocene reefs were inundated less than 11,000 year ago (Hopley 1995). Delays in

re-colonization occurred due to the need for larval recruitment from more distant sources (probably Coral Sea Plateau reefs), and as the result of initially poor water quality as regolith was removed from the Pleistocene foundations and as a result of very close proximity of the mainland of the time to the main reef tract. The major part of the Holocene growth took place only after 8,500 year. BP by which time the mainland coastline was close to its present position and well removed from the outer reef.

On the Great Barrier Reef, and generally many other coral reefs, the major period of Holocene accretion took place between about 8,500 and 6,000 years ago, when average vertical accretion rates of ca. 5 m per thousand years were achieved. Largely for hydroisostatic reasons (see Hopley 1982, chapter 13 for discussion) the pattern of Holocene sea-level rise over this period varied in different parts of the world. Over much of the Indo-West Pacific modern sea-level had been achieved by as early as 6,500 year. BP while in the Atlantic relative sea level may have continued to rise right up

Coral Reefs, Fig. 5 An evolutionary classification of Holocene coral reefs

to the present time, though at a considerably slower rate after 6,000 year. BP. Reefs have responded in different ways with three models recognized (Neumann and Macintyre 1985; Guilcher 1988):

- Keep-up, in which the reef was able to accrete vertically at about the same rate as the rise in sea level and was never more than a few meters below sea level.
- Catch-up, in which the reef lagged behind the sea-level rise due to delays in recolonization and/or slow growth. At times these reefs may have been more than 10 m below sea level.
- Give-up, reefs which after becoming established in the early Holocene died off and remain only as drowned

carbonate banks. Various reasons have been put forward. That they became too deep because of the rapid rise in sea level is unlikely in the majority of examples as most would have remained within the photic zone of active reef growth, unless there were also an increase in turbidity (which would have limited the depth of reef growth). Many “give-up” reefs are on shelf edges and sediment shed from upslope reefs may have been one cause of their demise. In the Caribbean, in particular, it has been hypothesized that as sea level first flushed the shelf, a new wave of sedimentation and eutrophication was the cause of shelf edge reef decline (Macintyre 1988). In addition, at high latitudes

shallow shelf waters may also have killed off reef growth at the shelf edge.

Once coral reefs caught up with sea level then their upward growth phase was terminated and carbonate productivity has been directed into lateral rather than vertical growth.

An Evolutionary Classification of Holocene Reefs

It is possible to examine the growth of modern reefs by way of an evolutionary classification (Hopley 1982), based on the presumption that the majority of reefs are located over pre-Holocene reefal foundations at no great depth and with an irregular morphology resulting from both the original growth form of the last period of reef growth and the erosion which has taken place during subsequent exposure. This presumes transgression by the sea over the foundations and a sea-level rise which most reefs or most parts of reefs cannot match by upward growth (Fig. 5).

Three phases of Holocene reef development are recognized in the classification. In the juvenile phases, initial colonization takes place on the antecedent foundation and upward growth of the reef lags behind sea level rise, enhancing the original relief of the foundation. In the mature phases, reefs reach modern sea level and develop reef flats over the highs in the antecedent surface and especially around the windward reef margins where reef growth appears to be most rapid. One or more lagoons typify this phase but in the later stages of maturity, lateral transport of sediment from the productive margins leads to initial infilling of lagoons, masking of the inherited relief forms, and widening of reef flats. The senile phase is reached when lagoons are infilled completely, and lateral movement of sediment from the windward margins leads to progradation to leeward.

The basic classification is applicable to medium-size reefs growing from antecedent platforms with single depressions. Smaller reefs, where antecedent surfaces may lack a proto-lagoonal relief may develop along similar lines but because the reef flat initially developed around the reefal margins may occupy such a high proportion of the total reef area, any lagoon which forms will be shallow and quickly filled and the mature phases will be either bypassed or be present for only a very short period. In contrast, the largest reefs will be at the mature stages for the longest period because of the low ratio of productive margin to lagoon area. These reefs may also differ from the basic classification during the mature phase by having more than one lagoon.

A major subgroup of reefs are ribbon reefs which form distinctive barriers. They grow from linear foundations which are either discrete antecedent platforms or higher rims on much larger and usually deeper platforms. The basic feature

is depth of water behind the narrow reef flat which develops from the foundations. Although sediment moves to leeward, accretion is very slow and widening of the reef flat is retarded. However, the stages in the development of a ribbon reef can be equated with those in the basic classification.

Development of Coral Reef Zonation

Distinctive morphological and ecological zonation of coral reefs is a characteristic which develops only after the reef has reached sea level and commenced horizontal growth of a reef flat (Hopley 1982, chapter 10). During “catch-up” or even “keep-up” phases, the reef may be too far beneath effective wave base to allow the significant energy gradient from windward to leeward to exist. The reef may be a more homogenous environment of continuous coral cover with the only variable being the attenuation of light on the flanks and the development of more foliaceous light capturing colonial forms. As the reef reaches sea level, however, the contrast between windward and leeward sides is enhanced by sediment movement, accumulation of detrital features, and the colonization of the various ecological niches by distinctive life forms. Zones develop parallel to the reef front, their width and distinctiveness determined by the length of time the reef has been at sea level and the strength of the energy gradient (Fig. 6).

While the species which inhabit the various zones may differ geographically, the morphology of coral reef zones is similar worldwide and typically may consist of:

Fore-reef slope: Increasing light and wave energy are the controlling parameters on the deeper fore reef. At greater depth are flat, platey, and encrusting light capturing corals. Higher up the slope where light is not limiting branching forms may dominate. Moving into the higher energy wave

Coral Reefs, Fig. 6 The windward margin of a mid-shelf reef, Great Barrier Reef showing outer living coral zone with buttresses, algal pavement with isolated reef blocks, aligned and nonaligned coral zones

Coral Reefs, Fig. 7 Reef front dominated by *Acropora* sp. close to wave base. Mainly corymbose are found on the higher crests of the spurs with arborescent and plate-like forms within the deeper channel

zone at about 10 or 15 m, more compact or corymbose forms become dominant and coral cover is dense (Fig. 7).

Reef crest: Particularly on high-energy reefs the crest develops massive spur and groove morphology. Originally thought to be inherited from karst rillen type features developed at low sea levels, most drilling investigations have indicated a growth origin for spur and grooves. They have developed as a baffle against the wave energy and are self-perpetuating as the grooves act as surge channels along which sediment is swept. **Outer reef flat:** The coral covered tops of the spurs are continued onto the outermost reef flat as a living coral zone of encrusting and resistant growth forms up to about mean low water mark.

Algal crest: Particularly on very high energy mid-oceanic atoll reefs a rim built by crustose coralline algae may rise to almost mean sea level. On lower energy reefs the feature may be far less prominent consisting of a rubble pavement cemented by the coralline algae. Under even lower energy conditions turf-like algae may dominate in this zone.

Detrital zone: Beyond the algal pavement, and often deposited over it may be a morphologically diverse zone characterized by deposition of coarse material derived from the reef front. This zone can consist of imbricated clasts of branching corals forming low irregular banks parallel to the reef front. Where tropical storms are relatively frequent a more prominent ridge or rampart may develop and, if stable for sufficient time, its lower sections will become cemented. Also in this zone, and on the reef flat to seawards may be much larger boulders and reef blocks the largest of which may be more than 10 m in diameter. These are sections of the reef front broken off in major storms or by tsunami waves.

The inner reef flat: Behind the energy-absorbing outer zones, the inner reef flat may be another zone of dense coral growth. Where wave set up provides a steady flow of water over the reef crest this zone may display an alignment of

corals normal to the reef front. Elsewhere, at low tide pools may be moated by the rubble ridges or the algal crest and massive corals will be in the form of micro atolls.

Lagoons and back reef zones: In the deeper water of lagoons or back-reef, finer sand size sediment, which is swept across the reef flat, forms prograding sand sheets which may slowly bury lagoonal or leeward side patch reefs. This sand sheet may be up to 500 m wide and 10 m in thickness and is where much of the carbonate productivity of the outer reef is finally deposited. Beyond this patch reefs of various forms may rise from the sandy lagoonal or back reef floor. Each patch reef may have its own "reef flat" surrounded by an algal rim. In shallower lagoons reticulate reefs forming a network of anastomosing ridges may form an intricate pattern of reef growth.

Leeward reef slope: The high energy wave zone is lacking from the leeward side of the reef and coral growth even near the surface may be in the form of branching thickets. If the leeward slope descends into deep enough water, at greater depth more light seeking platey forms may again dominate.

Fringing Reefs

Fringing reefs, attached to the mainland or to a high island, may have the weakest zonal development, especially where sheltered by offshore reefs or other islands. They are the commonest reef type with an area exceeding 320,000 km² or more than 50% of total reef area. Many grow in turbid waters but can still flourish as long as sediment does not settle and smother the corals. However, because of the greater attenuation of light the vertical zonation of the reef front may be compressed into less than 10 m water depth.

Fringing reefs were formerly considered to be the simplest of reef forms, growing outwards from the mainland or island shoreline as originally advocated by Charles Darwin over 150 year ago. However, over the last 20 year a considerable amount of drilling and dating of fringing reefs has been undertaken and they have been shown to have a complexity which matches that of other reef types.

Because they have a foundation on which to grow immediately sea level stabilizes (the island or mainland shore) many fringing reefs have reef flats older than those of nearby offshore reefs. On the Great Barrier Reef micro atolls older than 6,000 year BP are found on many fringing reef flats. However, reef establishment, growth and internal structure can show considerable variation. The structural classification (Fig. 8) is based on the results from Australian fringing reefs, but records from fringing reefs elsewhere in the world suggests that it has a wider application. Three basic types are recognized:

1. Simple reefs formed from the foundation on the lowest portion of the rocky foreshore during the transgression. These reefs were developed while the sea level was still

Coral Reefs, Fig. 8 A structural classification of fringing reefs

rising. Most of their development has gone into upward growth over the rocky slopes of the island, following the transgression. After the still-stand period and when the reef had reached sea level a small amount of outward growth may have been possible over the reef's own fore-reef talus slope. On the whole, such reefs are growing from relatively deep clear water and reef flat development is therefore limited due to the great vertical extent of these reefs. The structure is thus one of a basal framework unit immediately over rock and then a small biogenic detrital frontal unit with thin reef flat veneer.

2. Reefs developed over preexisting positive sedimentary structures. Reefs have long been regarded as requiring hard substrate for initiation. However, there is increasing evidence that the presence of even a muddy sedimentary structure with positive relief may greatly enhance or speed-up reef flat development. Such sedimentary structures may be in the form of terrigenous mud-sand banks or barriers, lee side sand spits attached to islands, boulder beaches, deltaic bar gravels, and low angle Pleistocene alluvial fans. During the transgressive phase, even though a bank may have existed previously, no reef development is possible because of the inhospitable nature of the substrate. However, once the rocky shores of the adjacent island or mainland are inundated reef colonization takes place rapidly on these shores at shallow depth. Progradation of the reef is then rapid over the preexisting structure with hard substrate now being provided over

the sedimentary base by the fore-reef talus from the prograding reef front. The structure of such reefs is thus one of a basal terrigenous sedimentary unit, an inner framework with a prograding carbonate detrital unit extending over the terrigenous base, and an upper, thin, generally less than 4 m, reef flat framework veneer.

3. Reefs developed over more gently sloping substrate, particularly where older foundations of Pleistocene reefs may be present. In these instances, the reef foundation is initiated offshore from the present coastline, although would probably have started as a fringing reef as sea level would have been lower at this time. The rising sea level however, isolated this initial reef which continued to grow upwards during the transgressive phase as an offshore barrier. Possibly, because of poor circulation and terrigenous input, growth behind this barrier was very slow. After the still-stand and after the reef reached sea level, the outer reef became attached to the island by lagoonal infilling, this infill coming from both the land as a terrigenous unit and from the outer reef as a biogenic carbonate unit. Following the still-stand, some small outward growth may also have taken place. The structure is therefore one of a framework unit offshore from the present shore and an interdigitated terrigenous and biogenic detrital fill behind the framework. A thin, reef flat framework veneer may be present over the entire reef and a small reef front biogenic talus may also be present.
4. Davies and Hopley (1983) indicated that fringing reefs grew at rates comparable to middle and outer shelf reefs,

though usually at the lower end of the growth scale, that is, for framework construction in the range of 1–4 mm/year. This may be in part a reflection of the greater proportion of massive as opposed to branching framework. As with outer reefs, the fringing reefs showed a bimodal detrital accretion rate, a lower range of 1–5 mm/year representing accumulation under normal weather conditions, but with higher rates up to 15 mm/year indicative of infrequent high energy cyclonic events. Fringing reefs generally show very low growth rates in shallow water, particularly when compared to the mid-shelf reefs which have both a protected situation and clear water. The lower rate for fringing reefs is probably a reflection of the turbid water conditions and periodic decline in salinities. However, at depths between 4 and 7 m, fringing reef growth seems to be at least equal to the rate of growth of both midand outer-shelf reefs. Below this depth, there appears to be a rapid decline in accretion rate. This is interpreted as the result of the high turbidity of inshore waters and rapid decline in light levels at these depths. Equivalent decline in growth rates for outer reefs takes place below approximately 15 m.

The Future of the World's Coral Reefs

While the store of knowledge about the functioning and evolution of coral reefs has expanded dramatically in the last 50 year, great concerns are currently being expressed about the health and status of the worlds reefs. It is estimated that 10% of coral reefs of the world have already been degraded beyond recognition; 30% are in a critical state such that they will be lost in the next 10–20 year; a further 30% are so threatened that they may disappear as living ecosystems in 20–40 year; and only 30% are healthy and stable (Wilkinson 1993).

The major reasons for this decline are from the anthropogenic stresses of organic and inorganic pollution, sedimentation, and overexploitation all of which are increasing with the exponential growth of human populations. Unfortunately, the majority of the most rapidly growing populations are in the tropics adjacent to coral reefs with subsistence economies at least partly dependent upon the reefs. However, superimposed upon these direct human pressures are the effects of global climate change with coral reefs being regarded as one of the most sensitive ecosystems to the predicted changes (Buddemeier 1993).

Many believe that coral reefs are already showing detrimental effects of climate change with a significant increase in coral bleaching as a response to unusually high temperatures detected globally over the last 25 year (Brown 1997; Hoegh-Guldberg 1999). Bleaching involves the expulsion of the symbiotic zooxanthellae (which gives the coral its color) from the coral tissue. Bleaching may be temporary and may

be an adaptation mechanism that allows more resistant strains of zooxanthellae to recolonize affected hosts. However, as the zooxanthellae are so important to the metabolic functioning of the coral, severe bleaching leads to mortality of whole colonies. Bleaching events appear to coincide with El Niño episodes with significant occurrences in 1979–80, 1982–3, 1987–8, 1991–5, and 1998. As El Niño events are predicted to become more regular and severe in a “Greenhouse” world, the associated short-term higher temperatures will be superimposed on a more general global warming, leading to increased stresses for coral reefs.

There are other harmful effects, including increased sedimentation from more runoff as tropical areas receive more rainfall, possible greater damage from increasing frequency and severity of tropical storms, and inhibition of calcification with CO₂ enrichment of ocean water. Planktonic and larval stages of many reef organisms, including corals, may be particularly susceptible to increasing ultra violet B (UVB) and shorter ultra violet A (UVA) radiation associated with decreasing levels of ozone in the upper atmosphere.

Rising sea levels can produce some beneficial effects. Inundation of reef flats which have been at sea level for 5,000 year or more may regenerate coral growth with reef flats contributing more significantly to carbonate production. Wave efficiency across reef flats may increase and sediments stored there may add to reef island construction. Some reef islands, contrary to popular opinion, can actually grow rather than erode as the result of rising sea level, but with reorientation of many islands also probable, the amount of inhabitable area with older cultivatable soils may decrease. Coral reef islands may not disappear, but their attractiveness for human habitation may decrease. Similarly, the structures which are coral reefs will not disappear as the result of anthropogenic stresses, but their dominance by animals (corals) may be overtaken by algae and other plants for which the Greenhouse scenario is more beneficial.

Coral Reefs, Emerged

David Hopley

Environmental Science and Management, College of Science and Engineering, James Cook University, Townsville, QLD, Australia

Corals and other reef-building organisms such as algae live within the photic zone, rarely deeper than 100 m and are limited upwards by intertidal exposure. However, well-preserved reefs emerged up to hundreds of meters above modern sea level are found in many parts of the world. All types of reefs are found emerged although the most common are fringing reefs occurring as terraces built over volcanic or other non-carbonate foundations (Fig. 1). Emerged barrier reefs appear to be rare, even in Indonesia which has both extensive, modern barrier reefs and numerous emerged fringing reefs (Tomascik et al. 1997). However, a section of the very long (2,000 km) Papua New Guinea barrier reef is emerged in Sabari Island (Fig. 2) to the north of the Louisiade Islands, and in the Trobriand and Lusancay Islands to the

north. Many emerged atolls occur in the Pacific (e.g., Henderson, Makatea, Mataiva, Nauru, Walpole) and in Indonesia (Maratua, Kakaban). Detailed descriptions of the geology and hydrogeology of many emerged reef examples can be found in Vacher and Quinn (1997).

Causes of Emergence

It is generally accepted that world sea levels were last ubiquitously above present during the last interglacial about 125,000 years ago and reefs of this age up to 10 m above present sea level have been reported from many quasi stable areas of the tropical world (e.g., Western Australia, parts of Tonga, Aldabra, Curacao). However, most of the world's reefs were exposed during the periods of glacially lowered sea levels (up to 150 m below present). Landforms produced during exposure have been a major influence on modern reefs (see “► Coral Reefs” entry). Emergence during the Holocene is more limited and for isostatic reasons is largely restricted to the Southern Hemisphere (Hopley 1982, 1987). For example, in the Great Barrier Reef region of north-east Australia emerged reefs of about 1 m and with an age of about 5,000 years are found only on the inner shelf islands and mainland and consist of coalescing micro atolls rather than fully developed fringing reefs as the period at the high level was short and followed a rapid post-glacial rise (Chappell et al. 1983).

The most spectacular suites of emerged reefs occur in areas of strong uplift at the margins of the world's tectonic plates (e.g., Ryukyu Islands, Barbados (Fig. 3), Papua New Guinea (Fig. 1), Indonesia). In mid-ocean areas uplift may also occur around hot spot swells or over asthenospheric bumps and is especially responsible for emerged atolls such as Ocean, Nauru, and Marcus Islands (Scott and Rotondo 1983). Long-term average rates of uplift may be as high as 5 m/ka with the highest reefs being of Tertiary age. For example, on Gunung Dirun Timur, Indonesia, terraces at 1,293 m are of Pliocene age (Tomascik et al. 1997). The majority of the best preserved reefs, however, are Pleistocene and because of the rate of uplift represent not only interglacial high stands but also reef-building periods at stable sea levels which were well below present. Emergence in these unstable areas continues with individual earthquakes having the potential to uplift living reef flats >2 m above sea level (e.g., Cortes 1993).

Modifications After Emergence

After emergence, coral reefs undergo changes to both the geochemistry of the reef fabric and to the morphology of the surface features. The original limestone deposited beneath the sea by coral and other plants and animals is largely

Coral Reefs, Emerged,

Fig. 1 Tectonically uplifted emerged reef terraces rising to 270 m on Misima Island, Louisiade Archipelago, Papua New Guinea

aragonite or high magnesium calcite. Once uplifted, however, the limestone is unstable in the freshwater vadose and phreatic environments and diagenesis through solution and reprecipitation as stable phase low magnesium calcite takes place (Matthews 1974). The open framework of the original reef becomes denser, infilled, and with greater cementation (Fig. C78, ► “Coral Reefs” entry). A coarse calcite crystalline structure is produced and in the uppermost layers a caliche horizon may be formed consisting of a distinctive brown crust with numerous micritic stringers (e.g., Hopley 1982), (Fig. C79, ► “Coral Reefs” entry). These processes also operated on reefs exposed during major sea level falls of the Pleistocene. Subsequent recolonization during post-glacial transgressions results in distinctive unconformities (see entry ► “Coral Reefs”), several of which may be found beneath modern reefs.

Erosion of emerged reefs may be relatively slow as the permeable limestone does not support surface drainage. Karst processes dominate but whether or not they have been rapid enough to produce large-scale relief features during the limited exposure of reefs emerged only by sea level fall as suggested by Purdy (1974) is debatable (Hopley 1982, Chap. 7). Bloom (1974) has suggested a facies control over rates of solution which would emphasize the constructional relief differences between reef rim and lagoon floor. Even in ancient reefs, structure may remain evident through facies guidance of solution. For example, the Devonian reefs of Western Australia were buried beneath Permian sandstones then truncated by a Mesozoic-Tertiary planation surface, yet uplift and rejuvenation has resulted in emerged reefs (the Limestone Ranges of the Canning Basin) which faithfully mimic the original morphology. Reefs which are permanently emerged by tectonic uplift do have sufficient time to produce

a range of karst landforms including cave systems, solution holes, and gorges. Their surfaces are an intricate network of holes and pinnacles either completely exposed or buried under soil and in some instances, commercially valuable phosphate deposits. Numerous local terms have been applied to this rocky relief (*makatea*, *feo*, *ironshore*, *champignon*, *platin*, *pavé*).

Emerged reef erosion may also take place horizontally with processes of bioerosion aided by some solution and physical abrasion creating an intertidal notch with overhanging visor (Fig. 2) at rates of up to 7 m/ka (Hopley 1982). Undercuts of several meters may occur and remain etched into the sides of emerged reefs as they are uplifted, providing erosional evidence of former relative sea levels, in addition to the reefs themselves (Fig. 3).

The Value of Emerged Reefs for Scientific Research

The accessibility of an ecological community and landform which is normally underwater, the relatively tight constraint in the relationship of a raised reef surface to a former sea level, and the accuracy of radiometric dating of constituent corals make emerged reefs highly valuable to several branches of scientific research. For example, they have been used in the development, calibration, and refining of dating techniques (e.g., Grün et al. 1992) but they have made particularly prominent contributions to the understanding of past eustatic sea levels, including those of the last glacial period. In some areas, at least, average uplift rates have remained constant over the latter part of the Pleistocene and are calculated from the present level of reefs for which the original eustatic level is well constrained (e.g., the mid-Holocene or the last

Coral Reefs, Emerged,

Fig. 2 Notch and visor cut into the emerged barrier reef of Sabari Island, Louisiade Archipelago, Papua New Guinea. The reef is probably last interglacial in age

**Coral Reefs, Emerged,**

interglacial). The uplift rate is then applied to other terrace levels which are dated by radiocarbon or uranium series methods to obtain a past sea level. These techniques were developed originally in Barbados (Broecker et al. 1968; Mesollela et al. 1969) and the Huon Peninsula in Papua New Guinea (Bloom et al. 1974; Chappell 1974). Results are continually being refined (e.g., Ota et al. 1993) and the degree of agreement between results from different areas justifies the basic assumptions.

Evidence from emerged reefs has also been used in geophysical modeling to develop theories of seafloor spreading, and processes associated with hot spots or melting anomalies,

including lithosphere loading, cooling subsidence, and asthenospheric bumps (McNutt and Menard 1978; Scott and Rotondo 1983). They have also aided in the understanding of upper earth rheology, flexure of the ocean lithosphere, and global isostatic responses.

Accessibility allows complete species inventories to be made and corals in particular may remain well preserved in even the oldest elevated reefs. From the data collected, the evolution of genera and species can be followed (Veron 1995) or the changes in ecological communities deduced from time-scales ranging through millions of years to the Holocene (Veron and Kelley 1988; Budd 2000).

Cross-Shore Sediment Transport

Richard J. Seymour
Scripps Institution of Oceanography
University of California at San Diego,
La Jolla, CA, USA

Cross-Shore Transport

Cross-shore transport refers to the cumulative movement of beach and nearshore sand perpendicular to the shore by the combined action of tides, wind and waves, and the shore-perpendicular currents produced by them. These forces usually result in an almost continuous movement of sand either in suspension in the water column or in flows at the surface of the seafloor. This occurs in a complex, three-dimensional pattern, varying rapidly with time. At any moment, some sand in the area of interest will have an onshore component while other sand is moving generally offshore. The separation of the total transport into components parallel and perpendicular to the shore is artificial and is done as a convenience leading to a simpler understanding of a very complex environment (see entry on *Longshore Sediment Transport* for shoreparallel transport).

Cross-shore transport has been well studied because of its importance to beach erosion. Unlike longshore transport, which is difficult to observe, cross-shore transport can result in large and highly visible changes in the beach configuration over intervals as short as one day. Because of the complexities associated with cross-shore transport, its magnitude and direction is usually inferred from changes in the elevation of the beach and the adjacent ocean bottom. Elevation profiles across the beach and through the surf zone are obtained with conventional surveying techniques, augmented as necessary with water depth measurements from a boat or other floating platform. A reduction in the amount of sand above mean sea level and a corresponding increase in the volume below this reference, for example, would be interpreted as offshore transport. If the beach volume increases at the expense of submerged sand levels, this implies shoreward transport. If the measurements were errorfree and the transport was entirely in the cross-shore mode, the amount of sand in the system should remain constant. Gradients in long-shore

Richard J. Seymour: deceased.

transport, however, can result in local accumulations or losses that make the precise assessment of cross-shore transport difficult.

Small cross-shore adjustments occur during each tide cycle along coasts with significant tide ranges. Much larger cross-shore transport events are associated with major storms, which may last for several days. These changes can be expressed in substantial beach or dune erosion or in rapid formation or migration of bars or other submerged formations. Intervals of smaller waves, and particularly swell of low steepness, can reverse the effects of storms and repair eroded beaches or move bars shoreward. These reversals have much longer timescales, perhaps as long as weeks or months. The accumulated effects of many storms during winter months and long intervals of low waves in summer, for example, can produce seasonal effects through cross-shore transport, as illustrated in Figure C87. Winter beaches may be characteristically lower and narrower with pronounced bars near the location of the largest breakers, while summer beaches are wider and with smaller, less-distinct bars closer to shore. Local wave climates, tide ranges, and sediment size influence these seasonal types, but the changes are a direct result of cross-shore transport (Fig. 1).

A number of investigations have been made in an attempt to predict what wave conditions would result in a shift between offshore and onshore transport. Much of the early work was done in laboratory wave tanks, using simple waves (Johnson 1949). Johnson associated the shift between the formation of summer and winter waves with a critical incident wave steepness in deep water. Other investigators found that the absolute size of the wave changed the critical steepness ratio. A second dimensionless parameter, the ratio of the wave height to the mean sediment diameter, was added by Iwagaki and Noda (1963) to account for scale. Seymour and Castel (1989) review the performance of six simple predictors for the direction of cross-shore transport, which involve some non-dimensional combination from among wave height and period, sediment size and fall speed, and beach slope. The best of these was successful only about two-thirds of the time. Bailard and Inman (1981) introduced physics into the study of

cross-shore transport with a predictive model that was based upon energetics, the balance between gravitation tending to move sediment downslope and the upslope stress produced by wave asymmetry. More recently, numerical models have been developed to predict storm wave erosion (Larson and Kraus 1990).

One of the earliest concepts about cross-shore transport concerned the tendency for waves to selectively move coarser sediment sizes shoreward (Cornish 1898). This results from the asymmetry of waves in shallow water (see entry on *Waves*). As waves approach the beach, the crests become steeper and the troughs longer. The shoreward flows under the crests are higher and for shorter duration than the offshore-directed flows under the troughs. Because larger sediment sizes require higher flow speeds to initiate movement, they tend to be preferentially moved by the shoreward flows. This was later refined to the null point hypothesis in which there is a stable offshore distance for a given sediment size, with a continuous gradation from coarse on the beach to fine in deep water (Ippen and Eagleson 1955). A number of field investigations have shown that sediment sizes are sorted in the cross-shore direction in nature, although bars and other features tend to produce locally mixed sizes as exceptions to regular gradation.

The study of cross-shore transport has resulted in the concept of an equilibrium underwater profile (Dean 1991). The shape of the offshore profile is approximated by

$$h(y) = Ay^{0.67},$$

where $h(y)$ is the depth at distance (y) and A is a scale factor related to the grain size distribution of the sand forming the beach. This is an engineering simplification that assumes, under the constant application of a given incident wave, a particular beach will evolve toward a certain profile shape. The incident wave can be further generalized to include all of the seasonal variation, resulting in a single equilibrium profile configuration for that beach. The actual profile may never achieve this contour because the incident waves are constantly changing. However, it is useful to coastal engineers

Cross-Shore Sediment Transport, Fig. 1 Cross-shore transport. The figure shows schematically how seasonal changes in wave climate affect beach profiles. During winter storms, the dry beach is eroded and seaward cross-shore sediment transport results in the formation of one

or more offshore bars. Typically, the envelope within which the shoreline ranges retreats seaward in winter and shoreward under the milder wave climates of summer

and scientists concerned with understanding the natural variability of beaches. The simple exponential model for the equilibrium beach does not include any provision for bars or other contour complexities such as rock outcroppings.

Cross-Shore Variation of Grain Size on Beaches

Philip D. Osborne
Golder Associates Ltd., Vancouver, BC, Canada

Definition

The distinctive sorting and cross-shore distribution of clastic beach particles is often evident even to the casual observer. The position at which a sediment particle comes to rest on a beach profile and the net patterns of particle size variation resulting from sediment transport processes have long been of interest to scientists and engineers attempting to understand

the fundamental relationships governing process and form on beaches.

Introduction

Cross-shore sorting and distribution of sediment in the coastal environment under waves, currents, and the effects of gravity may take several forms and have a broad range of manifestations in the sediment record. Sediment sorting on a range of scales is the basic process which leads to the formation of stratified layers of finer and coarser sediment (facies), which depend on and reflect the particular combinations of hydrodynamic processes, grain size and density distribution, beach slope and morphodynamic state, and sediment transport regime. The study of grain size variation and sorting of sediment on beaches is of significance to characterizing the morphodynamic behavior of beaches, to the interpretation of facies in the historical stratigraphic (geological) record, and has practical application in the design of beach nourishments, dynamic revetments, and other forms of coastal protection, as well as the assessment of environmental impacts of dredging and construction in coastal environments. Coastal studies involving estimation of beach slopes, equilibrium beach profile definition or sediment transport analysis by numerical or analytical modelling, depend on knowledge of the sediment grain size and its variation at a given site.

This entry reviews the long history of scientific fascination with the natural sorting of sediments which occurs on beaches, provides a brief review of methods of investigation, followed by summaries of the processes of selective sediment transport which result in cross-shore sorting and the observed grain size variation of different beach types from both field and laboratory investigations. Finally, several practical applications are provided with examples drawn from the literature.

Historical Perspective on Beach Particle Equilibrium and the Null-Point Hypothesis

The null-point concept was introduced to express stability of a beach profile and the associated distribution of sediment on the profile as a reflection of the equilibrium between asymmetric fluid forces (including wave asymmetry, steady currents, and the effects of percolation), bottom slope (gravity force), and the size and weight of sediment (Cornaglia 1889). Details of the original null-point hypothesis as expressed by Cornaglia did not predict particle and beach morphological behavior as observed, however. Bowen (1980) and Bailard (1981) improved on the original null-point hypothesis by applying Bagnold's (1966) sediment transport model. According to Bowen, sediment coarser than the equilibrium grain size on the local slope has a smaller value of β/W_s (ratio

of local slope and particle settling speed, descriptive of suspended load) and $\beta/\tan \phi$ (ratio of local bottom slope and grain friction angle, descriptive of bedload). Therefore, assuming a shoreward asymmetry in the velocity field, the term involving gravity is reduced, and coarser particles move shoreward to a position having the limiting slope. Similarly, finer particles should move offshore, as observed (e.g., Zenkovitch 1946).

Sediment transport and profile formation are more complex than are described by the theoretical models of Bowen, Bailard, and others. The concept of a sediment grain being in equilibrium with forcing requires the choice of appropriate temporal and spatial scales for analysis. Time scales as short as a single or even half wave cycle may be involved in the sorting and concentration of mineral grains according to size and density within beach laminae in the swash zone (Clifton 1969). At somewhat longer timescales, antecedent conditions, such as recent storms or periods of swell, spring/neap variations in tide level, water table variations, or a locally significant change in sediment supply or exposure can alter the shape and location of beach profile features and influence the distribution of sediments comprising the beach (e.g., Narra et al. 2015; Chen et al. 2012). At still longer timescales the relative sea level, sediment sources, prevailing climatology, and offshore bottom slope comprise the framework on which beaches and their particle size distributions develop.

Methods of Investigation of Grain Size Variation on Clastic Beaches

Studies of the grain size variation on beaches have most often been conducted by direct in-situ sampling followed by laboratory analysis to determine the grain-size distribution typically using mechanical (sieving) or optical (laser diffraction or laser in-situ scattering transmissometer (LISST)) or photographic analysis methods. Field samples for laboratory analysis can be obtained by a variety of methods that include grab sampling and coring. Short (1984) for example, has investigated the morphology, texture and facies sequence on seven sand beaches, located in low, moderate and high wave energy, microtidal environments in southern Australia using box coring and Scuba observations. Similar work was conducted in non-tidal barred beaches in the Great Lakes and tidal beaches of Atlantic Canada by Greenwood and Davidson-Arnott (1972).

Sediment profile imaging (SPI) techniques have been used to photograph the interface between the sediment bed and overlying water column. The technique is used to measure or estimate biological, chemical, and physical processes occurring in the first few centimeters of sediment, pore water and the benthic boundary layer. Time lapse imaging (tSPI) is used to examine physical and biological activity over natural

cycles, including tides, storms and daylight or anthropogenic variables such as thin layer dredge disposal and feeding loads in aquaculture (see review by Germano et al. 2011).

Wang et al. (1998) reviews various direct methods of measuring sand size distribution under active transport in the nearshore. Conventional suspended-sediment sampling for grain size analysis has generally relied on mechanical pumping and suction techniques (e.g., Nielsen 1983, 1984). The acoustic backscatter and LISST techniques developed by Hay and Sheng (1992) and Agrawal et al. (1996), respectively, are generally capable of estimating vertical profiles of sediment concentration and mean grain size simultaneously with higher temporal and spatial resolutions than pumping, suction, and trapping techniques and have been fairly widely applied in nearshore experimental studies. Limitations with acoustic and laser scattering techniques occur in the breaker zone due to the presence of bubbles. Therefore, Wang et al. (1998) obtained suspended sediment samples throughout the water column in the surf zone using the streamer-trap technique (Kraus 1987) to examine the vertical and temporal variation of sand size distribution under breaking waves.

Sorting and selective transport processes can also be measured effectively using tracer techniques. Sand size sediment tracers include optical detection of magnetic or fluorescent tracers with both natural and synthetic materials (e.g., Smith et al. 2007; Black et al. 2007). Larger particles such as pebbles, gravel and cobbles may be monitored using magnetic particles (Hatfield et al. 2010; Osborne and Chen 2005) or Radio Frequency Identification (RFID) Tags embedded in natural particles (e.g., Osborne et al. 2010).

Laboratory studies involving mobile bed physical models provide a controlled approach for studying sorting processes and resulting morphological development of beach and nearshore environments (e.g., Jiang et al. 2015; Chen et al. 2012; Greenwood and Xu 2001; Tanaka 1989).

Various integrated numerical models for nearshore sediment transport and morphology change now incorporate the effects of variable grain size fractions, sorting, bed armoring and the effects of the vertical structure of bed sediments (e.g., Deltares 2016). Lagrangian particle tracking methods coupled with 1D, 2D, or 3D hydrodynamic models can be used to evaluate grain sorting and selective transport processes in a wide range of environments (e.g., MacDonald et al. (2006)).

Processes of Selective Sediment Transport

The equilibrium profile depends on the sorting (standard deviation) and shape of the sediment as well as its size. Poor sorting results in less percolation and flatter profiles compared with well-sorted sediments of the same size (Krumbein and Graybill 1965; McLean and Kirk 1969). The sorting

processes themselves are dependent on the particle properties as well as the hydrodynamics. Sand-sized particles are sorted according to differences in densities, sizes, and shapes of the sediment particles. Four basic processes of dynamic equivalence or selective sorting act on beach sediments (Komar 1989; Hughes et al. 2000). Settling equivalence, hydraulic equivalence (Rubey 1933), or suspension sorting is the principle that permits a larger grain of lower density to be deposited simultaneously with smaller grains of higher density. Entrainment equivalence or selective entrainment (Komar and Wang 1984) refers to the difficulty of entraining smaller and heavier particles within a matrix of comparatively larger and lighter particles. Smaller particle size can be a direct factor in reducing particle mobility in terms of both relative exposure to flow and larger size of pivoting angle. Selective transport refers to the differential rate at which particles are carried by a flowing fluid by virtue of their position in the flow. Dispersive pressure equivalence or shear sorting refers to the process in which coarser grains tend to migrate upward to zones of lower shear while finer and denser grains move downwards to the zone of maximum shear (Bagnold 1954). The operation of such selective processes in the swash zone may lead to heavy mineral enrichment particularly in erosional episodes.

Part of the cross-shore selective sorting of sediment can be attributed to the patterns of orbital motions under waves as they shoal. Orbital motions under a Stokes-type wave, for example, consist of a forward orbital motion of short duration but high velocity under the crest while the return flow under the trough is slower but of longer duration. Cornish (1898) hypothesized that Stokes asymmetry might explain the shoreward movement of coarse particles and the seaward movement of fine particles. The idea has been verified in experiments (Bagnold 1940) and modeled with some success (Horn 1992). A grain may move incrementally shoreward by falling back to the bed before a wave nearbottom orbital trajectory has completed its half-cycle. A grain that is thrown into suspension and falls to the bed in a longer time than onehalf the wave period may be deposited seaward of its initial location (Dean 1973; Nielsen 1983). Ahrens and Hands (2000) compared sediment stability values with the maximum near-bottom velocity under the breaking wave trough, U_t , calculated with Stream Function Wave Theory to reliably discriminate onshore and offshore sediment transport. Large absolute values of U_t are associated with high suspended load and bedload transport offshore by undertow, and small absolute values of U_t with net onshore bedload transport. Although most of the attention has been focused on the dominant incident waves that arrive at the outer edge of the surf zone, the relative roles of waves of different lengths or frequencies in the selective sorting process in the nearshore zone has not been investigated in detail.

Both field and laboratory experiments have been used to examine the vertical and temporal coupling between the sediment in transport and the near bed fluid motion to gain further insights regarding the fractionation process (see review by Greenwood and Xu 2001). Osborne and Vincent (1996) demonstrate the importance of the phase coupling between the unsteady flow at different elevations and the vertically varying instantaneous suspended sediment concentrations in determining the direction and magnitude of sediment transport in combined waves and currents over rippled beds. Prototype scale wave flume measurements document distinct horizontal fractionation of sediment by size (Greenwood and Xu 2001). Sediment became progressively coarser onshore and progressively finer offshore in the wave flume from the same homogeneous source suggesting that the sorting is explained by suspension transport alone and is controlled by: (1) an increase in the proportion of fines and a decrease in mean size with increasing elevation above the bed and (2) vertically stratified sediment transport with net onshore transport near the bed and net offshore transport at higher elevations.

Cross-Shore Variation in Grain Size and Sorting

Mean grain size may decrease both shoreward and seaward from the plunge point at the base of the swash zone at sandy shores. A secondary coarsening of sediments has been observed on the offshore bar, where wave breaking is initiated (e.g., Fox et al. 1966; Greenwood and Davidson-Arnott 1972). Gravel and coarse sand lags as well as heavy mineral placers can also develop in the troughs or embayments between nearshore bars due to the interaction of waves with strong longshore currents and rips (Komar 1989). Recent laboratory experiments by Çelikoğlu et al. (2006) seem to mimic patterns observed in several field studies showing that finer material tends to be deposited on the crest of bar-type beach profiles, with coarser grains accumulated on the foreshore, trough, ridge, and toe sections. Finer materials settled on the foreshore and crest of step-type profiles while coarser grains were deposited on the ridge and toe sections.

On sandy beaches, mean grain size typically decreases up the foreshore, as a reflection of the diminishing swash intensity. Sediment sorting is poorest (standard deviation of sizes is largest) where energy dissipation is greatest. Skewness is most positive (or least negative) also at the plunge point, indicating a mixing of an over-abundance of fines with coarser sediments, relative to a lognormal distribution of sizes. Bascom (1951) observed a similar pattern, with the additional finding of the second coarsest beach material on the summer berm, and hypothesized that deposition occurred by wave uprush that had overtopped the berm crest and subsequent winnowing of finer fractions by wind. Edwards

(2001) has examined size variation and sorting of sandy beach sediments from more than 274 beaches in five regions of the globe. Edwards found that typically average grain size decreases from inshore (zone of breakers and currents) towards the backshore with foreshore and backshore sands better sorted than inshore sands. Edwards also found that terrigenous beaches are finer than carbonate beaches. Wider coastal plains exhibit finer and better sorted sediments.

In one of the more comprehensive and systematic studies of the relationship between size distribution, beach facies and morphodynamics, Short (1984) examined the variation in sediment texture and facies both within and between seven beaches in South Australia. Short found that low-energy reflective beaches are limited in lateral and vertical extent and in facies to beach laminations separated by coarse step deposits from finer nearshore cross-lamination facies. Moderate-energy intermediate beaches characterized by rip circulation possess increasingly wider surfzones with ridge and runnel and bar-trough facies separating the beach and step facies from the more extensive nearshore sequence. High-energy dissipative beaches may have 500 m wide surfzones containing multiple bar-trough topography. Fine beach laminations with backwash structures grade into 4–5 m thick bar-trough sequences then the extensive nearshore facies. As wave energy increases from low ($H_b < 1$ m) to high ($H_b > 2.5$ m) the vertical extent of the beach to nearshore sequence increases from < 10 m to approximately 30 m, and the width from 100 m to several kilometers. Consequently one would expect higher-energy paleo-beach sequences to be represented more by diagonal than vertical facies sequences.

The overall range in grain-sizes present on a beach has significant implications for both the cross-shore distribution of sediment and the form and behavior of the beach. Beaches with a broad mixture of sediments from silts, sands, gravels, cobbles and boulders often have a composite profile with a distinct break in slope between the upper foreshore where coarse sediment prevails and the low-tide terrace where finer sediment is more prevalent. Sediment size distribution on mixed beaches is responsible for beach hydraulic conductivity, which in turn, controls the beach profile and groundwater flow and also for modifying swash zone asymmetry (e.g., Mason and Coates 2001). High beach permeability leads to asymmetry of swash, such that swash is stronger during the up-rush than during the backwash. This effect tends to roll both gravel and sand shoreward during the up-rush, but mobilizes finer material seaward during the backwash, effectively stranding gravels higher on the beach with each successive wave. Mixed sediment beaches behave differently than either pure sand or pure gravel beaches. For example, a mixed-sediment profile will reflect more energy than both a sand beach (due to a steeper gradient) and a gravel beach (due to less energy dissipation through infiltration) (Mason and Coates 2001). Mixed beaches also exhibit distinctive

armoring in which gravel and pebbles form a thin surface layer over a more homogeneous mixture of sand, pebbles and gravel (Finlayson 2006).

On lower energy beaches with a broad distribution of sediments including cobbles and boulders, or beaches where sediments are simply too large to be re-distributed by the wave climate (such as Puget Sound or in sheltered estuaries), the beach profile may become reverse graded with the presence of lag stones on the lower profile (Finlayson 2006; Jackson et al. 2002; Nordstrom 1992). Lag stones are large boulders that erode from adjacent coastal bluffs and are deposited on the beach face rolling down the steep beach face due to gravity and forming a beach armor or lag deposit at or near the break in slope. Sediment size decreases both landward and seaward of the lag armor.

Beach sand sampled at transects across the active profile at Terschelling (North Sea barrier island of The Netherlands) showed consistent cross-shore pattern of grain size distribution over a period of 19 months (Guillén and Hoekstra 1996). The proportion of sample in each grain size fraction (50 micron increments) showed a distinctive cross-shore pattern, unique for each size fraction and termed the equilibrium distribution curve. The distribution of the fraction across the profile, relative to the total presence of the fraction, expresses the probability concept in cross-shore sorting.

Field studies of the spatial/temporal relationships between sand size distribution and morphology have been conducted by Sonu (1972) and Katoh and Yanagishima (1995) and others. More recently, Narra et al. (2015) conducted field studies of the spatial (cross-shore) and temporal (seasonal) variation in d_{50} by weekly sampling of sediments on Barra Beach, Aveiro. They found that sediments were typically coarser in the intertidal zone and breaker zone while generally decreasing offshore. A distinct coarsening in d_{50} was observed in foreshore sediments after storms and generally a greater variation occurred in winter months (storm season). Greater variance in d_{50} was also observed in the mid portion of the profile, whereas the extreme ends (both onshore and offshore) showed a tendency for less variation. Similar studies have been conducted by Medina et al. (1994) at “El Puntal” Spit, Santander, Spain. Principal component analysis of sediment samples and beach profile variability was used to conclude that spatial variability of both sediment and profile data are strongly related and each sediment size responds to the same hydrodynamics differently. Beach profile recovery following a storm started with the movement of fine material from the bar crest.

Application

Geomorphologists, engineers, and planners need to reliably project structural and beach fill performance, in terms of

offshore and longshore losses of beach material, or the change in beach profile or character of the beach face, after the material is sorted by natural processes acting over a period from years to decades.

Dean (1990) illustrates the application of an understanding of equilibrium profile behavior is useful to design and evaluation of coastal engineering projects including design of beach nourishments using empirical correlations between the profile parameter and the dimensionless fall velocity which is dependent on sediment size. Applications include analysis of shoreline position change, profile evolution, sediment redistribution and the effects of structures, under changes in water level, wave heights, and sand size variation.

Sediment supplied in a nourishment to Terschelling, The Netherlands, caused a coarsening (20–40 μm) of the sediment in the zone directly affected by the nourishment (Guillén and Hoekstra 1997). Six months after the nourishment, the grain size distribution across the profile was nearly the same as the original, and no significant effects of the nourishment could be recognized in the median grain size. Individual grain size fractions displayed a temporal evolution more complex than the median size, and significant changes, unrelated to the sand supplied, were observed. Overall results of Guillén and Hoekstra (1997) indicate that the shoreface nourishment only had a short-term and localized impact on the sediment distribution. Some months after the nourishment, the former grain size distribution was reestablished. On a yearly perspective, the natural variability of the sediment was higher than the changes caused by the nourishment.

Understanding sediment size distribution and its variability is also of relevance to assessing the impacts of construction in the marine environment (e.g., Dean 1990), the effects of sand mining (e.g., Hilton and Hesp 1996), and dredging and disposal at sea (e.g., Germano et al. 2011).

Studies of grain sorting also have relevance to understanding the formation of placers, which may have economic or intrinsic value (e.g., Komar and Wang 1984). Understanding the processes that cause size variation of sediments across a beach profile and the impact of the material composition on shore morphology is key to wise management of coastal resources.

Large and often devastating tsunamis as well as hurricane related storm surges can mobilize and redistribute substantial amount of coastal sediments, changing coastal morphology and sorting sediment in the process. Chen et al. (2012) conducted laboratory experiments in a wave flume to investigate changes to beach profile and mean grain size caused by tsunami-like waves. Their results showed that sand suspension and erosion were caused mainly by sheet flows when water retreats from the beach, whereas offshore sandbars, composed mainly of coarser sand, formed mainly from

the run-down hydraulic jumps caused by interactions between retreating water with the waves in the undulating tail of the tsunami. Similar studies (e.g., Chen et al. 2012; Lario et al. 2010) can assist in the interpretation of tsunami and major storm deposits in the historic record and contribute to the understanding the potential impacts of future events.

Summary

The cross-shore sorting of noncohesive sediment often results in distinctive visual patterns as well as the formation of a variety of sedimentary structures (or facies) and morphological features. Beaches exhibit a wide range of variation in sediment type and distribution which is often reflected in their morphological characteristics and behavior. Generally, average grain size decreases from inshore (zone of breakers and currents) towards the backshore with foreshore and backshore sands better sorted than inshore sands. Sediments are typically coarser in the intertidal zone and breaker zone while generally decreasing offshore. As wave energy increases from low ($H_b < 1$ m) to high ($H_b > 2.5$ m), the vertical extent of the beach to nearshore sorting sequence increases from < 10 m to approximately 30 m and the width from 100 m to several kilometers. The sorting process is controlled by a range of hydrodynamic processes (e.g., waves of different frequency and of variable symmetry and nearshore currents) as well as the grain size and density distribution of available sediment, beach slope and morphodynamic state of the beach.

Methods for investigation of grain size variation on beaches have advanced from direct sampling and physical/mechanical laboratory analysis to include optical (laser diffraction or laser in-situ scattering transmissometer (LISST)) or photographic methods; the latter techniques also including in-situ methods that avoid significant disturbance of the sediment structure. Numerical models for sediment transport now incorporate many of the effects of variable grain size fractions and can be used to evaluate sediment sorting along transport pathways.

Understanding sorting and distribution of sediment has significance with respect to characterizing morphodynamic character and behavior of beaches and for the interpretation of facies in the geological record. The topic also has practical application to the design of beach nourishment, shore restoration, and coastal protection, as well as in the assessment of environmental impacts of dredging and construction in coastal environments. Coastal studies involving estimation of beach slopes, equilibrium beach profile definition, or sediment transport analysis by numerical or analytical modelling also depend on knowledge of the sediment grain size and its variation at a given site.

Cusplate Forelands

Stephen J. Craig-Smith
School of Tourism and Leisure Management,
UQ Business School, The University of Queensland,
Ipswich, Australia

Cusplate Forelands are accretionary features, which occur on many coastlines of the world; Cape Kennedy (Cape Canaveral) on the east coast of the United States and Dungeness on the south coast of Britain being but two of

the more well-known examples (King 1972). While they vary considerably in shape and size they are generally triangular in outline with the base attached to the coastline and the apex facing the open sea or ocean. Although similar in overall shape, cusplate forelands must not be confused with cusplate spits; the former are cusplate forms which have grown by progradation, usually with nested shore-parallel beach ridges. Cusplate forelands are related to beaches, tombolos, spits, and barriers but whereas the related accretionary features tend to smooth out the coastal outline cusplate forelands accentuate coastal irregularities.

Formation

A number of theories have been forwarded to account for their origin. They may develop in the lee of an offshore island that shelters a segment of the coast in the shadow of the predominant oncoming wave front (Bird 1984). Waves are refracted to either side of the offshore island and concentrated wave energy affects the mainland shore to either side. Immediately behind the protective island diminished wave energy allows longshore moving sediment to accumulate. If the offshore island is sufficiently near the mainland the cusplate foreland may extend to the island itself in which case a tombolo develops. This has been observed in South Australia at Gabo Island. Here a cusplate foreland developed, it then joined the offshore island to form a tombolo and subsequent storm breaching made it a cusplate foreland once more. Formation in the lee of a protective offshore island however is only one way in which they can form.

More difficult to explain are cusplate forelands which develop on an open coastline with no protective offshore islands (Steers 1964). The east coast of England affords many examples of this type. Lowestoft Ness (the most easterly point of the British mainland) is one such feature. Whereas the cusplate forelands formed in the lee of protective islands remain relatively stationary, forelands with no such protection can, and very often do, migrate along the coast (Russell 1958). Surveys in the British Isles have tracked such features migrate along a coastline many kilometers. Banacre Ness in Suffolk has moved northwards by some 2 km over the last 100 years in spite of the dominant longshore drift being to the south (Robinson 1965). In some cases, the longshore migration has oscillated with periods where a foreland has migrated in one direction followed by periods where reverse migrations have occurred (Hardy 1966). Occasionally two adjacent cusplate forelands on an open stretch of coast have migrated in opposite directions. Such variations and contrary movement defy simplistic explanations relating foreland development merely to longshore drift.

While beach drifting and dominant waves are important, offshore current residuals and changing seafloor topography

are significant contributory factors. Offshore from the British east coast examples can be found of bank and channel complexes developed by the ebb and flood of the tide. Ebb- and flood-dominated channels tend to be separated by sand banks and adjacent to the apex of each foreland can be found an offshore sandbank trending toward the coast (Robinson 1964). Over time any change in the position of the offshore bank has resulted in a change in the position of the foreland, albeit after a short time lag. The supply of sediment arriving on the beach from the offshore bank is greater than the removal of the sediment along the beach and hence the local build-up of sediment at the landward termination of the adjacent sand bank. The movement of sand onshore from the adjacent sandbank together with wave refraction caused by the offshore sand bank itself accounts for the creation of the foreland and can account for its movement along the coast, which may be in a contrary direction to the main longshore drift.

Surface gravel, which is often present on the British cuspate forelands, is usually found in ridges—it is the tracing of these shingle ridges, which gives a clue to both their formation and migration, (Lewis and Balchin 1940). The shingle moves along the surface of the beach and accumulates in the area of lower wave energy. While the offshore sandbanks offer less protection than adjacent offshore islands the lesser influence on wave refraction is made up for by their contribution of sediment to the adjacent coastline.

Dalmatian Coasts

Dieter H. Kelletat

Institut für Geographiedidaktik, Fachgruppe der Didaktiken der Mathematik und der Naturwissenschaften, Universität zu Köln, Cologne, Germany

Definition

The term “Dalmatian Coasts” refers to a prototype of a primary coast by ingression of the rising postglacial sea into a relief of coast-parallel anticlines and synclines from a young orogenesis, named after the landscape of Dalmatia (Croatia, former Yugoslavia, Adriatic Sea, Mediterranean; Charlier 2010). In the eastern Adriatic Sea, this coastal landscape extends for 400 km from Rijeka in the north to Dubrovnik in the south. Single islands are up to 60 km long but only a few km wide.

Elongated cuestas may build the island chains instead of anticlines. Narrow channels between long islands are called “vallone” or “canale” (from the Italian word for channel or valley), and the Dalmatian Coast therefore is named canale or vallone coast, as well (Fig. 1). The coastlines of the central part of Croatia, built up by Mesozoic limestones, show only very little forming by true littoral processes (Pikelj and Juračić 2013). Beaches are missing as well as extended cliffs. The first is because of the small discharge or limited discharge area in a limestone environment with

strong karstification and the second because of a weak surf energy along the Adriatic Sea or inside of the canale and vallone with small fetch. Therefore, the coastlines exactly follow a contour line of an older relief, formed during longer periods of terrestrial denudation. Partly drowned karst features (dolines, uvala, poljes; Suric et al. 2005, 2014) decorate some of the coastlines, in particular along the mainland coast, where fresh water karst springs at the coast or even under the sea are numerous. The overall picture of the Dalmatian Coast gives the impression of submergence and down warping. Indeed higher coastal terraces or deposits from earlier interglacial sea-level highstands are missing. This picture will change very little during a further sea level rise or sea level fall. In the first case, the ingression will drown another depression, while the outermost islands will disappear under a rising sea level (Furlani et al. 2014), and in the second case, new island chains will emerge, while canale or vallone transform into inland depressions.

Conclusion

This type of coastline is rare; another large example is the Island of Sumatra with the Mentawai Islands parallel in the Indian Ocean. The terms “Dalmatian Coasts” as well as “vallone” and “canale” are not generally in use outside of the Adriatic Sea, although they exist in different dimensions worldwide.

Dams, Effect on Coasts

Jiyu Chen

Department of Geography, East China Normal University, Shanghai, China

People have constructed dams, weirs, or barriers on rivers to utilize and manage water resources for thousands of years. The utilization of water energy also has a long history, such as waterwheels and watermills, etc. The initial dams were used to control water resources and to supply water for irrigation and domestic purposes. Later, the energy of rivers was harnessed behind dams to power primary industries directly, and more recently still, hydroelectricity has been generated using water held in reservoirs, allowing the impoundment and regulation of river flow. The modern era of major dams dates from the 1930s and began in the United States with the construction of the 221 m-high Hoover Dam on the Colorado River. But in the last 50 years there has been a marked escalation in the rate and scale of construction of large dams

all over the world, made possible by advances in science and technology. Some major rivers in the world have been intensively manipulated in this way.

Today, approximately one-third of the countries of the world rely on hydropower for more than half of their electricity supply. The hydropower provides 20% of all electricity globally. If this electricity were produced by the combustion of fossil fuel, carbon dioxide emissions would increase by 2 billions tons a year. The construction of dams on rivers, as an infrastructure of national economy, plays an important role in controlling flood, hydroelectricity generation, irrigation, navigation, water supply of industry and agriculture, etc. There is no doubt that the construction of large dams has been successful in achieving their socioeconomic benefits. However, dams alter river hydrological regimes, accordingly induce structure and function changes of ecosystems, and inevitably have marked effects on nature and ecological environment of river drainage basins. An estuary is the only pathway of materials from the drainage basin into the sea. The coastal area far away from dams is the sink of riverine freshwater, sediments, and nutrients. Dams on rivers alter their downstream material discharge into the sea, accordingly induce impacts on estuaries and the coastal zone, such as estuarine channel evolution, the actions between runoff and tide, coastline changes, saltwater intrusion in estuarine and land salinization in delta areas, and ecosystem variations in estuaries and seas. Thereby, damming has positive and negative socioeconomic effects, but in the coastal area it has more negative effects.

Status of Dam Construction

The International Commission on Large Dams (ICOLD) defines *large dams* as usually >15 m from foundation to crest. Dams of 10–15 m can also be defined as large dams if they meet the following criteria: crest length of 500 m or more; reservoir capacity of at least 1 million m³; maximum flood discharge of at least 2,000 m³/s; “specially difficult” foundation problems, or “unusual design.” *Major dams* meet one or more of the following criteria: at least 150 m-high; havin a volume of at least 15 million m³; reservoir capacity of at least 25 km³; or generation capacity of at least one gigawatt.

Based on the definition above, there are some 45,000 large dams, most of which were built in the past 50 years, that now obstruct the world’s rivers. There are 306 major dams in the world today and 57 are planned in the near future (Revenge et al. 1998). The most active phase of large dam construction was in the period between 1950 and the mid-1980s, when 885 dams were completed on average each year. At the end of 1960, there were 7,408 such dams

registered. By 1986, the total had reached 36,562. Of those constructed, 64% were in Asia, with no less than half of the world total in China. Excluding China, most of the new structures have been built in the temperate zone, but tropical and subtropical countries such as Brazil, Mexico, India, Thailand, Indonesia, Zimbabwe, Nigeria, Cote d’Ivoire, and Venezuela have also become prominent in dam construction. Of these dams 79% are less than 30 m in height, and only 4% exceed 60 m. In total, the world’s major reservoirs were estimated to control about 10% of the total runoff from the land in the 1970s. That figure had risen to 13.5% by the early 1990s (Postel 1996) and must be nearing 15% today. The world’s largest impoundment, the 8,500 km² Volta Reservoir behind Ghana’s Akasombo Dam, flooded 4% of that nation’s land area. There are 10 watersheds with more than 5 major dams (Table 1).

To date, China has built almost half (22,000–24,000) of the world’s estimated 45,000 large dams, and remains one of the most active dambuilding countries today. Over 22,000 of the estimated 85,000 significant reservoirs and dams in China are considered as large dams, though there are perhaps a few million small-scale and localized water diversions, check dams and weirs built by local collectives or individual farmers that are unrecorded. China has thus built more than three times the number of large dams in the United States and over five times the number in India. Virtually, all these dams were built since the founding of the People’s Republic of China in 1949, as only 22 large dams existed before that time. The water resources controlled about 100 billion m³, risen to 565 billion m³ today. At least 90 dams over 60 m are under construction, including the Three Gorges dam on the Yangtze (175 m) and Xiaolangdi on the Yellow River. The utilization rate of river water resources increased to 19.9% in 1997, while the Yellow, Huaihe, and Haihe River are all over 50%, and the Haihe River is nearing 90%. In the United States, 5,500 large dams make it the second most dammed country in the world.

Dams, Effect on Coasts, Table 1 Watershed with more than five major dams

Yangtze (China)	6

Effects of Dams on Coast

Alternation of Material Discharge into the Sea

Dam construction on a river changes the flow regime of almost the entire river, both changing its seasonal variations and/or reducing its overall volume, and further change and/or reduce sediment and nutrient outflow. Consequently, almost all parts of the estuarine and coastal environment can be impacted by changes to flow, sediment, and nutrients.

First, damming and reservoir construction change water discharge into the sea. The nature of the impacts depends on the design, purpose, and operation of the dam, among other things. For instance, following construction of the Aswan High Dam on the Nile River, Egypt and Lake Powell River dam on the Colorado River, USA not only altered the seasonal variations of natural flow but also reduced its overall water volume into the sea. One well-documented example of additional stresses created by dams pushing an ecosystem toward collapse has been documented in San Francisco Bay. Prior to 1850, approximately 34 km³ was discharged on average into San Francisco Bay from the San Joaquin and Sacramento River systems. Today, there exists more than 20 km³ of water storage capacity in the Central Valley. Approximately 40% of the flow in these Central Valley rivers are removed for local consumption and 24% is pumped from the San Francisco Bay Delta and exported to Southern California and the Central Valley. Less than 40% of the river flows are now discharged to the Bay (Nichols et al. 1986). In the extreme drought of 1977, releases dropped to 100 m³/s, from the customary dry season discharges of 400 m³/s.

Second, because of damming, sediments are intercepted in reservoirs behind dams and reduce sediment discharge into the sea. Before the Aswan High Dam, the Nile River carried about 124 million tons of sediment to the sea each year, depositing nearly 10 million tons on the floodplain and delta. Today, 98% of that sediment remains behind the dam. The construction of the Three Gorges Dam on the Yangtze River, China, will not change total water discharge into the sea, just change seasonal distribution of runoff, but will reduce sediment outflow by approximately 20%. Otherwise, besides reducing sediment discharge, dams may also change the grain size of sediments, large amounts of wash load are intercepted in reservoirs, reducing the supply of fine-grained sediments to estuaries.

Dams not only alter the pattern of downstream flow and sediment (i.e., intensity, timing, and frequency) they also change nutrient regimes. Nutrients carried by runoff and sediments discharge changes with water and sediment outflows. The Colorado, Nile rivers have weak nutrient levels, probably because of high abstraction rates from large reservoirs, leaving little discharge into the sea.

Dams, Effect on Coasts, Fig. 1 Effects of dam construction of rivers on coast

Dams alter the conditions of water, sediment, and nutrient discharges into sea, leading to huge impacts on the environment and ecosystems in estuaries and on coasts (Fig. 1), such as coastal erosion, saltwater intrusion, and position changes of mouth bars in estuaries, nursery ground for many valuable fishes. Dam construction on an upstream river, although it does not alter overall volume of outflow, changes its seasonal variations and reduces sediment discharge, which all have profound effects on a river mouth and its adjacent coast.

Coastal Erosion

A coastline is dynamic and constantly changing due to coastal erosion and accretion, and its change rate is determined by natural processes, such as rough seas, sea-level rise, high tides, nearshore currents, runoff, as well as human developments that can restrict or accelerate the volume of sediment available for shores. A constant supply of sediment is necessary for depositional coasts to form and be maintained along this coastline. Many human activities reduce the supply of sediment that reaches the sea and, in turn, deprive coasts of replenishment. These activities include dam construction and other developments. Lack of sediment replenishment creates greater vulnerability for coastlines that have always been subject to varying levels of erosion. A principal coastal concern today and in the foreseeable future is coastal erosion. It is estimated that 70% of the world's sandy shoreline are eroding (Bird 1985). In the United States, the percentage may approach 90% (Leatherman 1988). This worldwide extent of erosion suggests, that eustatic sea-level rise is an important underlying factor, while many other processes, especially reduced sediment discharge into the sea, are important causes. Dam construction on rivers which intercepts sediments in reservoirs is one of the causes for reduced sediment discharge into sea. Because of dams, the sediment supply to an estuary and its adjacent coast is reduced, thus accelerating coastal

erosion. Even in a coastal delta of rich sediment supply, such as the Yangtze Delta, dams on the river may slow its accretional rate and gradually transfer to erosion.

Reduced sediment discharge directly affects coastal delta progradation, leading to loss of beach. For example, the slow accretion of the Nile delta was reversed with the construction of the delta barrage in 1868. Today, other dams on the Nile, including the Aswan High Dam, have further reduced the amount of sediment reaching the delta. As a result, much of the delta coastline is eroding by up to 125–175 m/year. Deltas below impoundments tend to shrink, reducing habitats, because of the capture of sediments by impoundments. The Nile Delta, Egypt, has shrunk at a rate of 125–175 m/year (Rozenfurt and Haydock 1993). The consequence of reduced sediments also extends to long stretches of coastline where the erosive effect of waves is no longer sustained by sediment inputs from rivers. Another example of this problem is along the mouth of the Volta River in Ghana. Akosombo Dam has cut off the supply of sediment to the Volta Estuary, affecting also neighboring Togo and Benin, whose coasts are now being eaten away at a rate of 10–15 m/year. The break-off water discharge in the lower Yellow River, China results in a sharp decrease of sediment discharge into the sea and its delta erosion. The major causes are damming and water transfer. The delta erosion of the Yellow River is an issue that needs to be urgently solved due to water and soil preservation and construction of Xiaolangdi Reservoir.

Accelerated coastal erosion has been detected as a result of regulated flows and dams reducing sediment discharge to the littoral cells. For example, local coastal regions along the Egyptian Mediterranean coast have experienced erosion rates that were three times greater than in the period prior to the Aswan High Dam (Smith and Abdel-Kader 1988). The construction of the Yangtze Three Gorges Dam will reduce sediment discharge and increase sediment transport capacity of flow in its estuary. Although it is of benefit to the sedimentation of navigation channel, it increases the action of bed sediments and leads to channel instability. Furthermore, it will increase coastline erosion and slow tidal flat accretion seaward (Chen and Xu 1995).

Saltwater Intrusion

Estuarine salinity varies with runoff, wind wave, and tidal current, and has complex spatial and temporal changes. Generally, estuarine salinity is higher during a dry season and is lower during flood season. There is a negative correlation with water discharge. Therefore, the water discharge is an important cause of saltwater intrusion. The change of water discharge leads to the alternation of the saltwater intrusion pattern: distance and intensity. Decreased

discharge rates can result in saltwater intrusion along estuaries, and pollute estuarine water and groundwater. It will affect the development of freshwater resources, especially domestic and agricultural water. In the delta area, because of impounding upstream, the aquifers underground becomes saline, and leads to a shortage of fresh groundwater. Besides, the alternation of seasonal distribution of runoff also affects seasonal saltwater intrusion, thus altering the position of estuarine balance zone.

Reduced water discharge due to dams undoubtedly intensifies saltwater intrusion in estuaries. However, seasonal regulation of dams may mitigate saltwater intrusion due to increased water outflow during the dry season. For instance, salinity intrusion is a problem in the Yangtze Estuary because of the vast area using water from the Yangtze. The water stored by Three Gorges at the end of the flood season will be released to increase the dry season flow and may help to alleviate the salinity problem in the estuary.

The intrusion of seawater into delta areas when river flows have declined due to reservoir impoundment is another common downstream effect. Construction of the Farakka Barrage on the River Ganges in India in 1975 has significantly increased the amount of cropland plagued by salinity problems in Bangladesh, as dry-season discharge has declined. Nationally, nearly 350,000 ha of land in Bangladesh was affected by salinity problems before the barrage was built, but by the mid-1990s this total had more than doubled to 890,000 ha. Downstream changes in salinity due to construction of the Cahora Bassa Dam in Mozambique are also threatening mangrove forests at the mouth of the Zambezi. Besides, reduced sediment discharge due to dams not only affects delta erosion but also intensifies land salinization.

Effects of Ecosystem and Biodiversity

A river's estuary, where freshwater meets the sea, is a particularly rich ecosystem. Some 80% of the world's fish catch comes from these habitats, which depend on the volume and timing of nutrients and freshwater. The riverine nutrients exist in water flow and sediments, carried and transported by flow and sediments, increase the nutrient level in estuaries and the adjacent sea. The decrease and alteration of the flows and nutrients reaching estuaries have marked effects on coastal and marine ecosystem and biodiversity, such as the nursery ground of fishes in estuaries and marine fish catch. The alteration of the flows reaching estuaries because of dams is a major cause of the precipitous decline of sea fisheries in many estuaries of the world.

The influence of diminished freshwater outflow to bays, estuaries, and coastal wetlands has become generally accepted during the past decade. One well-documented example of additional stresses created by dams pushing an

ecosystem toward collapse has been documented in San Francisco Bay. This reduction in freshwater inflow contributed to a drop in phytoplankton biomass to less than 20% of normal, and zooplankton was also significantly reduced. These conditions resulted in striped bass, one of the key indicator species of the health of the ecosystem, being reduced to the lowest recorded levels (Nichols et al. 1986). Water withdrawal on the North Caspian had the following effects (Rozengurt and Hedgpeth 1989): (1) the mean salinity increased from 8 to 11 ppt; (2) the estuarine mixing zone was compressed and moved up to the delta; (3) the nutrient yield, especially phosphorus, and sediment load were reduced by as much as 2.5 and 3 times, respectively; (4) biomass of phytoplankton, zooplankton, and benthic organisms were decreased by as much as 2.5 times; and (5) a substantial part of the Volga flood plain that served as a nursery ground for many valuable fishes was transformed into drying swamps or deserts. The regulation of the Volta River in Ghana by the Akasombo and Kpong dams has led to the disappearance of the once-thriving clam industry at the river's estuary, as well as the serious decline of barracuda and other sport fish. The effects of increased salinity on fishes of the Nile Delta have been documented that out of 47 commercial fish species in the Nile prior to the construction of the Aswan High Dam, only 17 were still harvested a decade after its completion. The annual sardine harvest in the eastern Mediterranean has dropped by 83%, probably the effect of a reduction in nutrient-rich silt entering that part of the sea. The effect of lowered nutrient input is generally the greatest in the first year of life of the fishes.

Decreased discharge rates can result in an increase in salinity in estuaries and change the composition of species in this zone. The Danube Delta, central Europe, coastline is receding at a rate of up to 17 m/year, threatening benefits from tourism down to bird life. The delta supports large populations of bird species that are generally widespread over Europe; some 170 species of birds breed in the delta, including pelicans, herons, ibises, and terns. Impoundments upstream, including seven major dams, on the 2,860-km-long river, channelization and the loss of the nutrient absorption capacity of upstream floodlands has meant that nutrients and other pollutants are affecting delta water quality. Bird populations are at a fraction of their historical numbers. So, although reservoirs may provide new habitat upstream their impacts on birds may be negative in the long-term.

The effect of dams on the ocean might be expected to be significant. The Three Gorges Dam on the Yangtze River in China is expected to reduce the productivity of the East China Sea, one of the largest fishing grounds in the world. It has been estimated that if the Yangtze River outflow is cut back by 10%, the cross-shelf water exchange will be reduced by 9%

with a similar reduction in the onshore nutrient supply. Primary production and fish catch in the East China Sea is expected to diminish by a similar proportion (Chen 2000).

Conclusion

Dam construction on rivers is a great act that human conquers nature and modifies nature. It has twofold effects: positive and negative. The positive roles are irrigation, power, flood control, and water supply, etc. In the meantime, it also leads to negative effects on environment, involving entire river basin, estuary, coast, and sea. The effects of dams on coast include coastal erosion, saltwater intrusion, ecosystem, and biodiversity, etc., and these effects are profound and mostly negative.

Deltaic Ecology

John Rybczyk

Huxley College of the Environment, Western Washington University, Bellingham, WA, USA

A System Overview

Deltas are depositional areas where rivers meet the sea, often forming extensive, coastal, alluvial fans. Although there is much variability, deltas tend to develop where high-energy rivers deposit their sediment loads into shallow, low-energy marine systems or, more generally, where river energies exceed marine energies. For example, the Mississippi River discharges an average of 6.2×10^{11} kg of sediments per year into the shallow, low-energy waters of the Gulf of Mexico, allowing for the development of an extensive delta complex spanning 30,000 km². Although deltas can dominate the coastal landscape, they are by no means static; characteristically undergoing a cycle of growth, channel abandonment, and deterioration (Fig. 1). Thus, the ecological populations and communities associated with deltas are unique in that they are subject to powerful allogenic riverine and marine forces, and to the overarching pattern of the deltaic cycle itself. For this reason, an introductory discussion of deltaic ecology is best approached at an ecosystem level, which considers the interactions between the biota and the abiotic forces that simultaneously drive, stress, and subsidize them.

Ecosystem Types

Since an entire deltaic complex can span hundreds of kilometers, a wide variety of ecosystem types can be associated with them. Although natural upland habitats can be found along the landward edge of the delta and on the levees that form alongside stream channels, the systems that characterize and dominate deltas are wetlands. Wetlands are distinguished by; (1) the presence of water, either above the surface, or in the rooting zone, (2) hydric soils that develop under anaerobic conditions, and (3) vegetation that is adapted to wet conditions. Since deltas are ecotones where rivers meet the sea, concentrations of salts in the waters associated with these wetlands can range from hypersaline (>35 ppt salt) to fresh (0 ppt salt). In general, the hydroperiod (the pattern of water levels and flooding in a wetland) and the salinity control the types of wetland communities that can be found within a given delta.

In temperate zones, salt and brackish water marshes (marshes are wetlands dominated by herbaceous vegetation) characterize the saline habitats. Freshwater tidal marshes and swamps (swamps are wetlands dominated by trees) characterize either the inland regions of the delta or those areas dominated by freshwater inputs from the active delta lobe. Between latitudes 25°N and 25°S, forests called mangrove swamps characterize the saline habitats. The term “mangrove” is not a taxonomic term, but rather describes a group of 12 genera of woody halophytes adapted to growing in intertidal regions of the tropics. Mangroves show remarkable adaptations to salt and flooding stress, but not to freezing temperatures, therefore they are replaced by salt marshes in the colder temperate zones.

Deltaic Ecology, Fig. 1 The delta cycle. (Modified from Roberts 1997)

Primary Producers and Net Primary Productivity

For several reasons, wetlands associated with deltaic systems are among the most productive in the world. First, several types of primary producers (organisms that assimilate the energy from light to synthesize organic compounds) can be found within one wetland including; photosynthetic bacteria, algae (e.g., phytoplankton, periphyton, and macro algae), bryophytes, and vascular macrophytes ranging from sea grasses to trees. Second, delta systems receive multiple subsidies such as riverine inputs that supply nutrients, sediments, and freshwater, and tides that flush plant toxins from the sediments and maintain moderately aerobic conditions. Finally, although the vascular plants that dominate most wetlands are subject to the stress of periodic flooding and salt, they are still capable of relatively high rates of production because they have evolved numerous strategies that allow them to adapt to, or avoid entirely, anaerobic stress and high concentrations of salt. These strategies include the development of specialized tissue (aerenchyma) that transport oxygen down to the roots, and root-level micro-filters that prevent salt from entering a plant.

Ecologists typically quantify the productivity of a system by measuring its net primary productivity (NPP). NPP is defined as the rate at which biomass is accumulated by photosynthesizers, after accounting for losses due to respiration. NPP is most often expressed in units of carbon, or dry weight, per some unit of time. For example, primary producers in deltaic systems can have rates of NPP exceeding $2.5 \text{ kg m}^{-2} \text{ year}^{-1}$ (above ground dry weight). This is equivalent to rates of NPP measured in tropical rain forests (Whittaker and Likens 1973). Ecologically, the concept of NPP is relevant because it represents the total amount of energy available to heterotrophs, or secondary producers, in the system, assuming no other inputs from outside the system. In deltaic wetlands, rates of NPP are controlled by (among other things), solar radiation, temperature, nutrients, salinity, and the availability of oxygen.

Secondary Production

The biomass accumulated by primary producers in a wetland can be consumed directly by either herbivores, organisms that feed on dissolved organic matter, or detritus feeders (detritivores), and indirectly by carnivores. Secondary production is the rate at which biomass is produced by these consumers of primary production. Due to the inefficiencies of energy transfer, secondary production within a marsh system is much less than primary production, unless there are significant sources of organic matter coming into the wetland from outside the system. This can be the case in some riparian wetlands, for example.

It is estimated that almost 75% of primary production in marsh ecosystems is broken down by bacteria and fungi. Early studies suggested that secondary production in saltmarsh wetland systems was driven, in large part, by these detritivores feeding upon the vascular plants growing within a marsh (Odum 1980). However, more recent research suggests that a large fraction of secondary production in salt marshes may be directly linked to fauna that consume phytoplankton and benthic algae (Kreeger and Newell 2000).

Ecological Forcing Functions

Definition

Forcing functions are the exogenous variables that drive an ecosystem. For example, the sun is the ultimate forcing function that drives primary production, but of course, it is not unique to deltaic ecosystems. As mentioned earlier, deltaic ecosystems are unique because they are driven by powerful forcing functions that can either subsidize or stress them. For example, river flooding contributes to anoxic conditions in a wetland (a stress), but also brings nutrients to the system (a subsidy). The following section outlines several types of forcing functions that characterize and define deltaic ecosystems.

Pulsed Forcing Functions

Perhaps more than most systems, deltaic ecosystems are subject to pulses of energy, ranging from daily tides to once-a-century category 5 hurricanes, that subsidize the ecosystem. These energetic events, which occur at varying timescales (Table 1) affect primary productivity, material fluxes, and

Deltaic Ecology, Table 1 Hierarchy of pulsing events in deltaic systems. (Modified from Day et al. 1995)

Pulsing event	Time scale	Impacts
Avulsion	1000+ years	New delta lobe formation
Major river floods	50–100 years	Major sediment deposition Enhanced productivity
Hurricanes/ tropical storms	5–20 years	Major sediment deposition
Seasonal river floods	Annual	Sediment deposition Nutrient inputs Decrease salinity Enhance production Organism transport
Spring tides	Bimonthly	Organism transport
Storm events (frontal passages)	Weekly	Sediment deposition Organism transport
Daily tides	1–2 cycles per day	Drainage Enhanced marsh production Flushes accumulating salt and sulfides Organism transport

the evolution of the delta itself (Day et al. 2000). Daily tides flush accumulated salts and sulfides that inhibit plant growth, thus enhancing primary productivity. Higher tides, which occur during full and new moons, allow fish to utilize interior marshes for feeding. The sustained winds associated with cold fronts can profoundly affect the hydrodynamics and associated sediment resuspension and deposition in deltaic regions. Annual river floods distribute sediments, nutrients, and freshwater to deltaic systems and have been shown to be positively correlated with primary and secondary productivity. On a longer term, major storms such as hurricanes can deposit several centimeters of sediment onto deltaic marshes and can be a critical process for maintaining a balance between rates of sea-level rise and rates of marsh accretion. Major river floods, which occur only once or twice a century are also associated with substantial sediment deposition and even the channel switching that starts a new delta cycle.

River Switching, the Ultimate Pulsing Event

The initial growth of a deltaic lobe starts as river sediments fill in areas along the coast and marine shelf. Eventually, as the delta extends seaward, the existing river becomes longer, the channel slope to the sea decreases and becomes hydraulically inefficient, and the entire river switches to a new channel. This switching event (an avulsion) often occurs abruptly, during a major flood, for example, when an upstream levee is breached and the river captures a new, shorter, and steeper course to the sea. In the final phase of the delta cycle, water and associated sediments are directed to the new channel, and the old deltaic lobe deteriorates as rates of subsidence become greater than the rate that sediments accumulate (Fig. 1). Of course while the old delta is deteriorating, a new delta, associated with the new river channel, is forming. The rate of channel switching is governed by the characteristics of the river and the receiving basin. For the Mississippi River delta, perhaps the most studied in the world, the river changes course approximately every 1000 years. Although pulsing events like the ones described above control ecosystem dynamics on the short term, it is the ecosystem's temporal position within the delta cycle that ultimately controls it.

Subsidence and Sea-Level Rise

Natural rates of subsidence in many deltaic systems can be quite high due to the compaction, consolidation, and downwarping associated with the rapid deposition of alluvial sediments. This subsidence, plus the global eustatic sea-level rise (currently $0.15 \text{ cm year}^{-1}$), defines the rate of relative sea-level rise (RSLR). Some of the highest rates of RSLR ($1.1\text{--}1.3 \text{ cm year}^{-1}$) have been recorded in the Mississippi River delta of the United States. In wetlands, high rates of RSLR can lead to increasingly long periods of inundation that are associated with decreased primary productivity and

plant mortality. Therefore, RSLR can be thought of as a forcing function that stresses, rather than subsidizes a wetland ecosystem.

Deltaic wetlands can persist in the face of RSLR when vertical accretion equals or exceeds the rate of subsidence. The rate at which a wetland accretes depends upon sediment and nutrient supply, tidal range, vegetation, and climate. Current models suggest that coastal wetlands can remain stable against a RSLR rate as high as 1.2 cm year^{-1} (Morris et al. 2002). Since this rate is equal to or higher than the current rate of RSLR in many deltaic systems, this would suggest that these systems are sustainable. However, best estimates suggests that, due to the impacts of global warming, the eustatic sea levels could rise 48 cm by the year 2100 (Church et al. 2001). Recent studies have suggested that few deltaic wetlands would be able to keep pace with this predicted increase in sea-level rise (Day et al. 1999). Exacerbating this problem, reductions in sediment delivery have led to rapid wetland loss in many deltaic regions worldwide. This is discussed further in the next section.

Anthropogenic Disturbances

Although it is technically correct to position humans within an ecosystem, it is not out of order to consider some anthropogenic actions as allogenic forcing functions. For example, as previously discussed, seasonal river flooding deposits sediments onto wetlands that contribute directly to elevation gain, and counterbalance the effects of RSLR.

However, many of the world's major rivers that are responsible for the creation of deltas in the first place have now been dammed. This has not only trapped large amounts of sediments in the reservoirs behind the dams, but has also prevented the seasonal flooding that once distributed sediments onto the delta. For example, due to upstream dams, the sediment load has been reduced by 95% in Nile, Indus, and Ebro rivers, by 75% in the Po and Mississippi rivers, and by over 50% in the Rhone river (Day et al. 2000). Additionally, because of the creation of extensive levee systems along these rivers, the remaining sediment that does reach the coast often discharges directly into deeper waters of the receiving basin, rather than accreting on the deltaic plain. Finally, many wetlands in deltaic regions have become hydrologically isolated by dense networks of canals and spoil banks constructed during the past several centuries. Spoil banks impede drainage and often physically impound wetlands, thus preventing the overland flow of any remaining sediments into coastal wetlands. As an example, because of the combined effect of high rates of RSLR and decreased sediment delivery, wetlands in the Mississippi River delta complex are currently being lost at a rate of $100 \text{ km}^2 \text{ year}^{-1}$.

While the hydrologic alternations that reduce pulses are perhaps the greatest anthropogenic forcing function threat

to deltaic ecosystems, they are by no means the only ones. Other anthropogenic disturbances include eutrophication, organic enrichment, thermal pollution, toxic inputs, over harvest, and exotic species introduction. Also, because of their position in the landscape, deltas are, and always have been, desirable places to live, farm, and conduct commerce, and humans continue to encroach on these systems.

Toward the Conservation and Restoration of Deltaic Ecosystems

Deltaic wetlands provide numerous valuable services such as fisheries production, disturbance regulation, and water quality improvement to a global population that is increasingly concentrated near the coast and dependent upon its resources (Nuttall et al. 1997). Scientists and resources managers have become aware that, to prevent the further loss of these systems, landscape scale solutions directed toward the restoration of sediment supplies are required. Some of the more successful projects have included: (1) creating gaps in the artificial levees that line most distributory streams, (2) removing sea-side dikes to restore tidal flushing, and (3) creating large-scale diversions of river water to re-introduce nutrients, freshwater, and sediments to wetlands that have been hydrologically isolated.

The Caernarvon Freshwater River Diversion project in coastal Louisiana, USA, which has been operating since 1991, is one of the best examples of this third type of restoration. The project consists of a structure containing 5 m²-gated culverts that divert water from the Mississippi River into a part of the delta that was losing approximately 400 ha year⁻¹ due to high rates of RSLR. Construction was completed in February 1991 at a cost of US \$26.1 million, and the estimated net benefit for fish, wildlife, and recreation is over US \$9 million per year. In a 1998 project summary, the Army Corps of Engineers reported a net increase in marshland of 165 ha within a monitored area that originally contained 930 ha of marsh. Oyster and fish productivity, and waterfowl usage has increased dramatically as well.

Deltas

Shea Penland and Mark A. Kulp
Department of Geology and Geophysics, University of New Orleans, New Orleans, LA, USA

Deltas are coastal landforms comprised of subaerial and subaqueous packages of fluvial-transported sediments that have

Shea Penland: deceased.

formed an alluvial landscape by deposition at the mouth of a river. Deltas form at the coastal interface where riverine sediment supplied to the coastline is not removed by tides or waves. The term delta derives from Herodotus who, in the fifth century BC, noted a geometric similarity between the tract of land at the mouth of the Nile River and the Greek letter “Δ” with its apex directed landward (Moore and Asquith 1971). Although this distinctive morphology is absent in many river-mouth landscapes, the term has nonetheless been accepted to describe the geographical region near a river mouth and the sedimentary package that develops at a fluvial entrance into a depositional receiving basin.

Globally, deltas can be found on all continents and in all climates (Fig. 1). In a general sense, the locations of deltas are similar; at the terminus of a catchment basin that provides sediment load into an ocean, gulf, lagoon, estuary, or lake. Although a delta may form regardless of the size of the fluvial system or receiving basin, some tectonic settings are more conducive than others to the development of major deltaic landscapes. Using the Inman and Nordstrom (1971) tectonic classification of coasts, trailing-edge coasts typically have the largest drainage basins followed successively by marginal-seacoasts and leading-edge coasts. Of the 58 major river systems in the world with drainage areas greater than 10^5 km^2 , 56.9% are on trailing edge coasts, 34.5% along marginal-seacoasts, and 8.6% on leading-edge coasts.

Trailing-edge coasts provide a geologic setting favorable to delta development because of their tectonic stability and geologically old, low-relict terrains with extensive river systems that provide an abundant supply of sediment. Moreover, trailing-edge coasts often border broad continental shelves,

which provide ideal shallow-water platforms for the formation of deltas. Marginal-seacoasts typically provide a low-energy setting with many trailing coast characteristics that are conducive to delta development. However, the mountainous and immature drainage systems of tectonically unstable, leading-edge coasts with small catchment basins and low sediment supply generally limit the likelihood of extensive deltaic deposition. Table 1 lists the sizes and locations of the some of the world’s major deltaic systems.

Delta Types and Formation

Previous summaries of the world’s deltas have primarily focused on the major large deltas (e.g., Coleman and Wright 1975). A review of the recent literature on late Quaternary deltaic systems reveals that deltas can be classified into four basic types depending on sea-level stage (highstand or lowstand) and/or sediment supply (high or low) (Kindinger 1988; Boyd et al. 1989; Nichol et al. 1996). The four basic types of deltas are lacustrine, bayhead (or lagoonal), continental shelf, and continental margin. In an evolutionary sense, these four types of deltas can represent a developmental continuum. Thus, during a sufficiently long sea-level stillstand a fluvial system with adequate sediment supply could result in a lacustrine deltaic system that evolves into a continental-shelf margin deltaic system through progradational outbuilding.

Lacustrine Deltas

A lacustrine delta consists of deposits located landward of the coast or paralic zone within an inland lake or sea. The

Deltas, Fig. 1 Map showing the global distribution of major deltas. Note that most of the major deltaic systems are located along trailing-edge coastlines close to the equator. (Modified from Coleman and Prior 1980). Numbered locations refer to deltas listed in Table 1

Deltas, Table 1 Names, locations, and sizes of major deltas. (From, data compiled from Coleman and Wright 1975)

River	Location	Receiving body of water	Deltaic area (km ² × 10 ³)
Amazon (1)	South America	Atlantic Ocean	467.1
Burdekin	Australia	Coral Sea	2.1
Chao Phraya	Asia	Gulf of Siam	11.3
Colville (2)	North America	Beaufort Sea	1.7
Danube	Europe	Black Sea	2.7
Dneiper	Asia	Black Sea	NA
Ebro (3)	Europe	Mediterranean Sea	0.6
Ganges–Brahmaputra (4)	Asia	Bay of Bengal	105.6
Grijalva	North America	Gulf of Mexico	17.0
Hwang Ho	Asia	Yellow Sea	36.3
Indus	Asia	Arabian Sea	29.5
Irrawaddy	Asia	Bay of Bengal	20.6
Klang	Asia	Straits of Malacca	1.8
Lena	Asia	Laptev Sea	43.6
Mackenzie	North America	Beaufort Sea	8.5
Magdalena	South America	Caribbean Sea	1.7
Mekong	Asia	South China Sea	93.8
Mississippi (5)	North America	Gulf of Mexico	28.6
Niger (6)	Africa	Gulf of Guinea	19.1
Nile (7)	Africa	Mediterranean Sea	12.5
Ord	Australia	Timor Sea	3.9
Orinoco	South America	Atlantic Ocean	20.6
Paraná	South America	Atlantic Ocean	5.4
Pechora	Europe	Barents Sea	NA
Po (8)	Europe	Adriatic Sea	13.4
Red	Asia	Gulf of Tonkin	11.9
Sagavanirktok	North America	Beaufort Sea	1.2
São Francisco (9)	South America	Atlantic Ocean	0.7
Senegal	Africa	Atlantic Ocean	4.3
Shatt-al-Arab	Asia	Persian gulf	18.5
Tana	Africa	Indian Ocean	3.7
Volga	Europe	Caspian Sea	27.2
Yangtze-kiang (10)	Asia	East China Sea	66.7

environmental setting in such cases is typically a shallow-water basin with a low-energy regime. Along the Gulf of Mexico, the best example of a lacustrine delta is the Grand Lake delta within the Atchafalaya drainage basin of southcentral Louisiana. At the start of the nineteenth century

Grand Lake within the Atchafalaya Basin was a shallow, low-energy lake (Tye and Coleman 1989). However, by the 1950s a large lacustrine delta had filled this lake and started bypassing into the Atchafalaya Bay as a result of the progressively increasing Mississippi River flow into the Atchafalaya basin (van Heerden and Roberts 1988). Historically, if left uncontrolled, the Mississippi River would have avulsed from its modern course into the Gulf of Mexico past New Orleans to the Atchafalaya course located farther west. Other lacustrine delta examples are present within Lake Geneva and Lake Constance (Switzerland) (Müller 1966; Reineck and Singh 1973).

Bayhead/Lagoonal Deltas

Bayhead/lagoonal deltas are located in the upper reaches of the coastal zone. In many cases they represent an evolutionary step from a lacustrine delta during a sea-level stillstand or withdrawal, which allows the delta to build into the coastal or paralic zone. Bayhead-delta settings are typically protected by barrier-island systems or remnants of preexisting antecedent topography, resulting in a low-energy environment. Examples of bayhead deltas are found within the northern part of Mobile Bay Alabama (Kindinger et al. 1994), Trinity Bay, and San Antonio Bay Texas; (McEwen 1969; Donaldson et al. 1970; van Heerden and Roberts 1988).

Continental-shelf Deltas

Continental-shelf deltas develop during prolonged sea-level stillstands and/or a sea-level fall. These deltas build out onto the continental shelf. Trailing edge or marginal sea continental-shelf deltas typically are characterized by an abundant sediment supply and their geomorphology reflects the wave, riverine, and tidal conditions in which they develop. Examples of continental-shelf deltas include the Mississippi (US, Louisiana), the Ebro (Spain), and the Colville (US, Alaska) (Frazier 1967; Maldonado 1975; Naidu and Mowatt 1975; Alonso et al. 1990).

Continental-shelf Margin Deltas

Continental-shelf margin deltas are typically most well-developed during sea-level lowstands or formed by rivers with very large sediment loads during prolonged sea-level stillstands. The majority of shelf-margin deltas in the recent geologic record have developed during falling sea-level or sea-level lowstand conditions as river valleys lengthen, incise across subaerially exposed continental-shelf sediments, and discharge their sedimentary load at the shelf margin (Suter 1994). With sufficient sediment load and/or during lowstand conditions these deltas continue to build seaward, creating an apron of deltaic sediments along the shelf edge that extends the preexisting continental margin into deeper basinal waters. Numerous lowstand shelf-margin deltas, formed during the late Wisconsin sea-level fall and lowstand that culminated at

approximately 18,000 year BP, are found seaward of the Rio Grand and the Mississippi River deltas (Morton and Price 1987; Suter et al. 1987; Suter 1994). Sufficiently large rivers carrying substantial sediment loads may however, construct shelf-margin delta deposits during sea-level highstand conditions. An example of a shelf-margin highstand delta is the depocenter of the main stem of the modern Mississippi River delta, the representative “Bird Foot” delta (Boyd et al. 1989).

Delta Processes

Deltas result when sediment-laden fluvial water decelerates upon entering a receiving basin and sediment transport competence of the river is lost. Consequently, fluvial characteristics and river-mouth processes constitute an important controlling factor in the nature of deltaic deposition (Bates 1953). A consideration of fluvial processes is particularly important in deltaic environments where receiving basin processes such as wave and tide regimes are minimal. In such environments the primary fluvial factors, influencing the nature of deltaic deposition, include the volume of riverine discharge and transported sediment, as well as the textural character of the sediment load. Generally, the forces associated with these factors that dictate the character of fluvial-margin deposition are: (1) the riverine effluent inertia and diffusion, (2) friction between the sediment load and the floor of the receiving basin, and (3) density contrasts between the effluent and the receiving basin waters (Bates 1953; Wright 1977; Orton and Reading 1993).

Homopycnal Conditions

Homopycnal flow describes river discharges where the density contrast between riverine and basinal waters is small. Discharge patterns are most heavily influenced by inertia of the riverine water, which allows the effluent to radially spread into the receiving basin. As a result of deltaic progradation, fine-grained bottomset sediments are overlain by relatively coarser grained topset beds and river mouth-bar deposits, creating the classic coarsening upward depositional units common to deltaic systems. Gilbert (1884) first described this type of deltaic system in lakes of the western United States; hence, they are termed Gilbert-type deltas.

Hyperpycnal Conditions

Hyperpycnal discharge conditions occur when the riverine inflow is denser than the waters of the receiving basin. Consequently, the sediment-laden effluent moves along the receiving basin bottom as a density current. This type of discharge process is rare and typically restricted to deltaic systems rich in silt and coarse-grained sediments such as in the Bella Coola fjord delta of British Columbia (Kostaschuk 1985).

Hypopycnal Conditions

Hypopycnal discharge conditions occur when the riverine inflow is less dense than the waters of the receiving basin, a condition commonly present in lakes and inland seas. Most of the world's deltas form under hypopycnal conditions. In hypopycnal settings, as the riverine inflow enters the receiving basin it undergoes turbulent mixing resulting in the deposition of the sediment load. Finer-grained sediments are transported well into the receiving basin as the freshwater sediment plume disperses above relatively more dense basinal waters, whereas the relatively coarser grained sediments are deposited in close proximity to the river mouth. In shallow-water hypopycnal discharge conditions, friction between the receiving basin bottom and the riverine leads to multiple bifurcations of the distributary system. Conversely, in deep water during hypopycnal discharge conditions, buoyancy dominates during the dispersal of the effluent, producing elongated distributaries such as present at the modern Mississippi River depocenter (Suter 1994).

Delta Components

The delta plain is the subaerial and subaqueous zone where sediments are discharged from the alluvial valley and accumulate in the receiving basin. Typically, a delta plain is subdivided into an upper delta plain and a lower delta plain, each of which are characterized by different vegetation, morphology, and depositional processes (Fig. 2) (Reineck and Singh 1973; Coleman 1981; Elliot 1986). Many of the features of the upper delta plain are inherited from its alluvial valley. In the upper delta plain deposition is primarily fluvial and as the main stem of the river leaves the alluvial valley it discharges onto the upper delta plain and undergoes channel bifurcation. The vegetative landscape of the upper delta plain is a freshwater environment, generally beyond the influence of marine incursions created by the tidal regime of the receiving basin. The major landform includes distributary channels with their subaerial natural levees, point bars, and crevasse splays, as well as interdistributary environments characterized by low-lying swampy areas.

Seaward of the upper delta plain is the relatively lower relief of the lower delta plain that is within the realm of tidal incursion. The lower delta plain is the site of more active deposition through overbank flooding processes. Because the elevations of the natural levees are lower, channel crevassing and distributary shifting is a common and very dynamic process characterizing the lower delta plain. These processes disperse sediment from areas within the upper delta plain into brackish to saline environments of the lower delta plain. Distributary shifting common in the lower delta plain results in a complex distribution of multiaged distributary channels in all stages of evolution (Fig. 2). The lower delta plain

Deltas, Fig. 2 Schematic diagram showing the primary physiographic components and depositional environment of a delta. (Modified from Coleman and Prior 1980)

contains active and abandoned distributary channels in all stages of regressive and transgressive evolution (Penland and Suter 1989). Because the lower delta plain is a transitional environment influenced by fresh-water fluvial and saline marine waters the vegetative landscape generally contains species tolerant of both brackish and saline water.

Deltaic Sediments

In general, deltaic sedimentary packages contain a coarsening upward vertical stratigraphy that reflects seaward progradation of the delta into its receiving basin. At any given time there is typically a well-developed gradient of grain sizes extending seaward from the subaerial to subaqueous portions of a delta. The relatively coarsest grained material is deposited proximal to the river mouth where transport competence is highest, whereas the finest-grained material is carried farther seaward and deposited in more distal locations. Thus, as sediments are delivered to the receiving basin from the river mouth they accumulate in a subaqueous, fine-grained depositional zone referred to as the *prodelta*. The prodelta forms the platform across which deltas prograde and subsequently aggrade. The prodelta sedimentary package is a widespread laterally continuous interval primarily composed of the finest

sediment fraction transported by the fluvial system. Thus, the overall finest sediment is found at the base of the prodelta sequence and the whole sequence coarsens upwards. Moreover, the initial prodelta deposits are the thinnest at the base and the beds thicken upward as a result of deltaic progradation. Bioturbation of prodelta sediments is limited by the rate of deposition.

The delta front is located between the zone of fine-grained prodelta deposition and the more landward located, coarser-grained distributary mouth deposits of a progradational deltaic system. The relatively coarser-grained sediments of the delta front generally consist of interbedded clays, silts, and sands. This zone is dominated by the interaction of fluvial and marine processes, resulting in sand-rich accumulations landward of the advancing prodelta. The delta front also represents a zone of transition between deposits representative of progradation and aggradation.

In a progradational deltaic sequence, distributary channel deposits overlie the relatively finer grained delta front and prodelta deposits. The framework of distributary channels consists of distributary mouth bars overlain by natural levee deposits. Distributary mouth bar deposits are primarily subaqueous deposits that grade laterally into relatively finer grained deposits; locally, mouth-bar deposits may contain fine-grained beds within the generally sandy matrix of the

mouth bar. The presence of fine-grained deposits primarily represents deposition during low-flow conditions. During flood conditions, natural levee ridges can be over-topped and breached creating crevasse splays. These splays within the distributary network provide conduits for sediment dispersal into interdistributary bays and the origin of crevasse-splay deposits.

Interdistributary bay and marsh sediments are generally as volumetrically significant as prodelta sediments. The interdistributary area is a low-energy depositional environment and less dynamic than areas of the delta plain characterized by multiple channels, channel bifurcations, and channel avulsions. Interdistributary deposits characteristically consist of fining upward deposits consisting of clay-rich bay sediments overlain by organic-rich marsh deposits. This fine-grained depositional environment is punctuated by sandy depositional events associated with overbank flooding and crevasse splay events.

Delta Morphology

Although sediment delivery to a delta is by a fluvial system, it is ultimately the dynamic interaction of riverine and basinal processes that control the morphologic, stratigraphic, and sedimentologic variability of a deltaic accumulation. Water depth and basinal configuration, tidal range, wave climate, and coastal currents are the primary basinal processes that control delta morphology. The dynamics of these processes and complex interaction between them leads to a highly variable array of deltaic configurations (Coleman and Wright 1975).

One of the first and simplest attempts to describe deltaic variability as a function of processes involved depicts the morphology of river deltas as a function of sediment influx and marine processes such as waves and longshore currents (Fig. 3). The tidal regime of the receiving basin was not

considered in formulation of this model. Fundamentally, this model describes the processes leading to deltaic deposition as either constructive or destructive (Davis 1983). Deltas dominantly influenced by the nearshore wave climate are termed destructional, characteristically cusped shaped with poorly developed distributaries and well-developed strand plains such as in the Sao Francisco delta of Brazil. Intermediate between destructional and constructional forms, is the lobate-shaped delta, typified by the Niger delta of Africa. Lobate deltas possess well-developed distributary networks and a smooth coastal outline. Deltas that are strongly influenced by sediment influx are essentially constructional and are characterized by distinctive elongate distributaries. An example of this type of delta is the modern “Birdfoot” depocenter of the Mississippi River.

In the 1970s, new process-response approaches to understanding morphologic variability of deltas incorporated features of the constructional/destructional approach but also considered the effects of the receiving basin tidal regime. In the Galloway (1975) scheme a variety of previously documented delta morphologies (e.g., Fisher et al. 1969; Wright and Coleman 1973) were classified within the framework of a ternary diagram that effectively differentiated delta morphology as a function of sediment input, wave-energy flux, and tidal energy flux (Fig. 4).

Deltas dominated by sediment input are supplied by a large well-developed drainage system, capable of transporting large volumes of sediment to the deltaic coastline. Distributary switching is an important process, resulting in a highly constructive elongate to lobate deltas with straight to sinuous active and abandoned channels. The bulk composition of the sediment supply is muddy to mixed and the framework facies include distributary mouth bar, channel-fill sands, and delta-margin sheet sands (Table 2).

Deltas shaped primarily by waves are usually characterized by a small catchment basin with little sediment influx. The high-energy wave environment leads to winnowing

Deltas, Fig. 3 Schematic diagram showing the variation in deltaic geomorphology as a function of the relative influences of fluvial and marine processes. (Fisher et al. 1969, with permission of University of Texas, Bureau of Economic Geology)

Deltas, Fig. 4 Ternary classification of deltas on the basis of dominate processes and the resulting morphology. (After Galloway 1975)

of fine-grained sediments and leaves behind a relatively coarser-grained sediment fraction. Consequently, the bulk composition of wave-dominated deltas is typically sandy. The primary distributary channels are meandering and the framework facies are coastal barrier and beach-ridge sands (Table 2).

Deltas shaped primarily by tides are similar to wave-dominated deltas in that tidal currents winnow away much of the fine-grained sediments delivered to the coast. However, a fundamental difference is that tidally formed sand bodies are oriented shore normal. The distributary channels flare seaward and in some cases are straight and oriented parallel with the tides. The bulk composition of tide-dominated deltas is highly variable. The primary framework facies include fine-grained estuarine fill and coarse-grained sand ridges (Table 2).

Modern Deltas

Globally, modern deltaic systems are geologically young features that have formed since the initiation of late Wisconsin deglaciation at approximately 18,000 year BP. Although the development, existence, and evolution of deltas along modern coastlines is contingent upon sea-level change, sediment delivery, and marine processes, the timing of formation for modern deltas suggests that sea level has been a primary factor controlling delta development and stability (Stanley and Warne 1994).

Deltas, Table 2 Morphologic, stratigraphic, and sedimentologic characteristics of delta depositional systems that result in fluvial, wave, and tide-dominated systems. (Modified from Galloway 1975)

Characteristics	Fluvial-dominated	Wave-dominated	Tide-dominated
Geomorphology Channels	Elongate to lobate Straight to sinuous distributaries	Arcuate Meandering distributaries	Estuarine to irregular Flaring straight to sinuous distributaries
Sediments Framework facies	Muddy to mixed Distributary mouth bar and channel fill sands, delta margin sand sheet	Sandy Coastal barrier and beach-ridge sands	Variable Estuary fill and tidal sand ridges
Framework geometry	Parallels depositional Slope	Parallels depositional strike	Parallels depositional slope

At the height of the late Wisconsin glacial period approximately 18,000 year BP, sea level was approximately 120 m lower than present sea level (Fairbanks 1989). During this interval of lower sea level rivers crossed subaerially exposed continental shelves within incised channel systems. Large volumes of sediment were debouched along bordering continental margins and locally, thick and extensive shelf-margin deltas developed (Morton and Price 1987; Suter et al. 1987). Subsequently, as the late Wisconsin glaciers melted and sea

level rose, exposed shelves were flooded and transgressed with marine waters. Initially, sea level rose so rapidly that the global paralic zone was forced tens of kilometers landward. Marine processes at the leading edge of the transgressing marine waters reworked the formerly exposed continental shelf leaving a marine truncation surface and transgressive coastal-zone deposits in the form of ravinement surfaces and transgressive coastal marine deposits, inner shelf shoals, sand sheets, and shoreface ridges.

Following the initially high eustatic rise rates associated with deglaciation the rate of sea-level rise dropped below a critical threshold rise rate allowing global landward migration of the paralic zone. Beginning approximately 7000 year BP, the rate of sea-level rise appears to have slowed enough to allow for deltaic progradation and a relatively synchronous development of the world's deltas (Fig. 5). The temporal uniformity in delta development suggests a decline in the rate of sea-level rise, following the melting of late Wisconsin ice sheets, strongly influenced Holocene deltaic formation (Stanley and Warne 1997).

Deltas, Fig. 5 Graph showing the time of formation for latest Quaternary deltaic systems and ages of deltaic archeological sites in relation to deceleration in the rate of sea-level rise following the late Wisconsin sea-level lowstand. (Ages from Stanley and Warne 1997; sea-level curve from Fairbanks 1989)

Deltas and Society

Deltaic environments have played an important role in our global society. Deltaic environments served as the culture hearth for early civilizations throughout the world because of their tremendous variety of food resources such as fish and wildlife. Moreover, the rich alluvial soils of deltaic landscapes allowed for the establishment of bountiful crops vital to the establishment and expansion of early cultures (Stanley and Warne 1997). Today, deltaic wetlands that were more recently viewed as uninhabitable wasteland are once again considered to be of utmost ecological value. Additionally, ancient deltaic deposits are actively explored as they often contain a wealth of fossil fuels such as hydrocarbons and coal, resources that helped spur the industrial revolution and continue to be critically important to our modern technologically driven society.

However, as humans have populated the world's deltas, harnessed the rivers that built them by flood-control structures, and altered natural deltaic coastlines the delicate balance of these dynamic systems has been compromised. Deprived of water and sediment, most of the world's deltas are undergoing dramatic coastal land loss and habitat change as a result of anthropogenic induced as well as naturally occurring subsidence and rising sea level along coastal zones. As a result, a new multidisciplinary field of coastal restoration science is emerging as humans embark to rescue and effectively manage deltaic landscapes. The future of modern deltas will be dependent on our ability to balance environmental protection and economic development, while developing new restoration technologies for their maintenance and restoration.

Demography of Coastal Populations

George A. Maul¹ and Iver W. Duedall²

Definition

Demography of coastal human populations attempts to quantify the current and future number of residents living within 100 km of the shore country by country, and region by region.

Introduction

To most observers who live along a coast it seems clear that the resident human population is growing rapidly, but how fast is population growing? Will future growth be concentrated in the coastal zone? Do such demographics portend well for sustainable development?

To answer these questions we have combined the recent work of Burke et al. (2001), who reported the fraction of a country's population living within 100 km of the coast, with United Nations (2017) population figures to calculate the 2020 and 2035 coastal populations for 129 countries. Burke et al. relied on the work of the Center for International Earth Science Information Network (CIESIN, see reference in Burke et al.) at Columbia University, to obtain the coastal population fraction. In our work, we did not attempt to reanalyze the work of CIESIN. Rather country-by-country we multiplied the fractional coastal population reported in Burke et al. by United Nations 2020 and 2035 population values (United Nations 2017).

The United Nations based its calculated demographic projections for each country on birth, death, fertility rates, and age structure of the population. We assumed that the 2035 coastal population fractions would remain unchanged from the 2020 values reported by Burke et al. (2001). It is likely, however, that for some countries, such as the United States, coastal populations will grow faster than noncoastal areas (Culliton et al. 1990), as aging populations will live longer and will seek to live near marine environments. Thus the 2025 populations reported herein should be considered minimum values.

Coastal Properties and Demographics by Country and Region

Table 1 lists the results for the 129 countries (column 1) in thousands of people. The countries are grouped within eight geographic regions (Burke et al. 2001), with each country listed beneath the region. Coastal lengths and claimed Exclusive Economic Zone are from Burke et al. (2001), and the total population values (column 4) are from United Nations (2017). Each country's demographics are broken down into the 2020 and 2035 total populations, the 2020 and 2035 coastal populations (persons living within 100 km of the coast), the difference between 2020 and 2035 coastal populations (column 9), and the relative increase or decrease over the 2020 population (%). The footnotes at the base of Table 1 specify the calculations.

Surprisingly India not China has the largest coastal population, 364 and 411 million people for 2020 and 2035, respectively, or 13% growth in 15 years. Bulgaria, Latvia, and Lebanon will experience 11%, negative growth in their coastal population from 2020 through 2035. Fifteen other countries in Europe plus Japan will experience decreasing coastal populations 2035. All in all, only 23 countries are projected to have declining coastal populations in the next two decades or so.

Figures 1–4 show the overall 2020 and 2035 demographic trends for the eight geographic regions. Figure 1 shows the

total *coastal population* estimated for the year 2020, and that projected for 2035 in millions of people. Figs. 2 and 3 compare overall total population, by region, with the corresponding total *coastal population*, for 2020 and 2035, respectively. In Fig. 4 we present the *population increase per kilometer of coastline* for the eight regions summarized in Table 1.

Middle East and North Africa and Sub-Saharan Africa coastal populations will grow by 18% and 42%, respectively, from 2020 to 2035 (Fig. 1). Combined, these changes represent an addition of approximately 143 million people living in the coastal area by 2035 over the 2020 coastal population of approximately 496 million people.

The Asian region (which excludes the Middle East), which includes heavily populated China, India, and Indonesia, will experience relatively smaller percentage growth: 8%, by 2035. However, in absolute terms the Asian coastal region will be home to 1.7 billion people in 2035, an increase of 135 million over 2020.

North America, Central America and the Caribbean Islands, South America, and Oceania will experience increased growth by 10%, 13%, 22%, and 18%, respectively, or an increase of 81 million people by 2035; the calculated total coastal population in 2035 for these four regions is 572 billion (Table 1).

Europe is the only region where coastal populations may decrease rather than increase. In 2020 the European coastal population is estimated at 308 million people (Table 1); by 2035 we calculate that the coastal population to be 311 million, an increase of only 3 million people. The reason for the small increase in coastal population (1%) is due to population stability (zero growth rate) or in some cases negative population growth rates.

Figure 4 shows the 2020 and 2035 coastal populations normalized to coastal length, a factor that can indicate “environmental stress” (Culliton et al. 1990). By 2035 the regions of Asia, Middle East/North Africa, and Sub-Saharan Africa will contain more than 5000 persons per km of coastal length. The impacts of such a high density of people along a coast will include marine pollution, over-fishing, and loss of natural habitat.

Consequence of Increasing Coastal Populations

Much of humanity lives in the coastal zone, and probably has done so for millennia. That a 12% increase in coastal population, compared with a 13% increase overall by 2035, should be no surprise, given the uncertainty of such calculations. We estimate then that globally, the coastal populations will grow slightly faster than the overall population, but that the difference is not statistically significant. Clearly, however, Sub-Saharan Africa will grow their coastal populations much

more rapidly than the global average (42%), while Europe (1%) will be much less.

In terms of gross numbers, however, it is Asia, with a projected 8% increase translating to 1.3 billion more persons living in the coastal zone by 2035, that is of greatest potential environmental impact. Sub-Saharan Africa's 42% increase equates to 1 billion more people in their coastal zones. These two regions, totaling 2.3 billion more coastal dwellers between 2020 and 2035, account for 64% – almost two-thirds – of all population growth. Socioeconomically, it might well be argued that these two regions also represent the lowest per capita income of all Earth's people.

Rapid coastal population growth coupled with limited financial and natural resources is a well-documented recipe arguing against sustainable development (see Maul – *Small Islands* – this volume). The weathered mantra “Give a man a fish – feed him for a day; teach a man to fish – feed him forever” will not withstand the scrutiny of the population statistics in Table 1. Humankind requires resources to survive, infrastructure to provide protection from natural hazards, and a society to provide essentials of public health and governance. Coastal resources are finite, as is Earth's ability to provide in extra-coastal regions. Overfishing is perhaps only the first sign that coastal-dwelling humankind is growing beyond sustainable limits.

Demography of Coastal Populations, Fig. 1 2020 and 2035 coastal populations within 100 km of coast by region

Demography of Coastal Populations, Fig. 2 2020 total population (countries with a coastal zone) and 2020 population living within 100 km of the coast, by region

Demography of Coastal Populations, Fig. 3 2035 total population (countries with a coastal zone) and 2035 population living within 100 km of the coast, by region

While feeding burgeoning populations is an essential enterprise, “sustainable development” must also include some other aspects of quality of life. In many tropical regions, the great storms variously called hurricanes, typhoons, or cyclones have been the cause of more loss-of-life than any other natural hazard. In the twentieth century, an estimated 1,000,000 souls have been lost to this one hazard than any other. With 64% increase in coastal populations in Asia and Sub-Saharan Africa by 2035, the risk is substantially

increased. In extra-tropical environments, these storms are still extremely destructive, not to mention the intense winter storms of upper mid-latitude flailing against coastal populations. Modern weather forecasting with satellite and radar observations in developed countries clearly is mitigating the risk to coastal communities of such storms.

Another coastal natural hazard, tsunami waves, knows no latitudinal boundaries, as do tropical storms. Although often thought of as a natural hazard of the Pacific Basin, tsunamis

Demography of Coastal

Populations, Fig. 4 Population per 1 km of coastline, 2020 and 2035, living within 100 km of the coast, by region

are in fact a source of great risk to coastal dwellers in all oceans, especially the Mediterranean and the Caribbean Seas. The great Lisbon earthquake and tsunami of 1755 would cause orders-of-magnitude more loss of life and socioeconomic disruption today if repeated in the North Atlantic Ocean.

Sea level rise due to thermal expansion of the upper layer of the ocean and to the melting glaciers will affect many countries, especially small island countries. Coastal flooding and saltwater intrusion are two consequences for countries with sloping shorelines. There is considerable variation in the overall calculated rate of global sea level rise, ranging from 1.7 mm/year to a high of 3.17 mm/year (IPCC 2017). The current public takes little notice, as the rise in sea level is hardly perceptible; however, future coastal populations will surely suffer depending on location, geography, and increased rates of sea level rise.

Beyond the natural hazards, those of geophysical origin, are the biogeographical hazards of intense coastal population growth and development. Humankind produces domestic and industrial wastes. These wastes can be hazardous to others of our species – producing numerous and well-known toxicities or communicable diseases. Given that the greatest growth of our species is in two coastal regions – Asia and Africa – it is reasonable to project increased reports of water-borne public health outbreaks. Implantation of acceptable waste management practices for example, alone, is potentially of a magnitude to overcome all financial resources of intergovernmental banking agencies in the next quarter-century.

Finally, we briefly compare future coastal population with future tourist population. According to Goldberg (1994) world tourism in 1970 grew from 160 million to 341 million people in 1985, or an annual growth rate of 5%. If one projects this growth rate exponentially from 1985 through 2025, total world tourism will grow to 2.5 billion, or approximately four times the increase in world resident coastal population calculated (Table 1). While it is problematic whether world tourism can sustain such a large growth and surely not all tourists seek only the coastal zone, the calculation does demonstrate that some coastal countries may need to either limit tourism or develop new or more efficient infrastructure to accommodate

the growing numbers of people living and/or recreating on beaches or in water. For example, the economies for many of the countries in Central America and Caribbean Region, and Oceania are driven by tourism. Thus such countries will need to carefully consider their options in the areas of waste disposal, habitat, and pollution in order to optimize conditions leading to clean and natural environments to sustain both the local and national economy.

Conclusions

It is not our intention to paint a bleak picture of our coastal future – but of a realistic scenario of population growth and environmental and socioeconomic consequences. Earth is remarkably resilient to humankind's activities. Our planet's ability to dilute pollution is not infinite, and our coastal impacts will exacerbate the global problem. Surprisingly, the global population growth is not significantly different from what is reasonable to expect in the coastal zone – that is within 100 km of the shore. The environmental and socioeconomic impact however may be more. The essence of this increased potential impact is simply gravity.

The rivers and streams that bring mid-continent discharges to the coastal waters are essentially pressure gradient forces driven by gravity. Communities that discharge their wastes into coastal waters, whether by gravity or pumping, inject their wastes into littoral ecosystems. The 355,271,000 ($\pm$) more of us living within 100 km of the coast between 2020 and 2035 will impact the very small fraction of Earth's surface area we consider home to 40% of humankind. Surviving that percentage growth is a taxing but not insurmountable challenge.

No other challenge will tax the intellect of humankind more than population growth. It is comforting perhaps that the challenge in the coastal zone is not more daunting than in other regions. However, oceanographers have long known that coastal ecosystems are particularly at risk from human activity. These fragile natural communities are increasingly seen as endangered, not only because of those living within 100 km of the coast, but also because of all others, whose effluent reaches the coast.

Depth of Closure on Sandy Coasts

Andrew Morang and William A. Birkemeier
CERC, US Army Waterways Experiment Station,
Vicksburg, MS, USA

Kraus et al. (1999, p. 272) proposed the following definition of the *depth of closure* (DoC):

The depth of closure for a given or characteristic time interval is the most landward depth seaward of which there is no significant change in bottom elevation and no significant net sediment exchange between the nearshore and the offshore.

Figure 1 illustrates the concept by showing the change in the nearshore profile resulting from a single storm. In this case, the DoC is 6.45 m as there is little change in the bottom deeper than this. Thus, the DoC separates the active nearshore from a less-active offshore and therefore is an important parameter in many coastal engineering projects. For example, in order to build out the entire beach profile, nourishment quantities are often computed by multiplying the desired added beach width by the DoC. In another application, numerical models of beach change use the DoC as an offshore limit to their computations. Because of its importance, the

Depth of Closure on Sandy Coasts, Fig. 1 Example nearshore profile change caused by a single storm event with the DoC located at the deepest point of significant bottom change (in this case, <6 cm). (Data from the Corps of Engineers' Field Research Facility at Duck, NC, USA)

DoC is a topic of considerable research on how to predict and measure it, and on what it represents with respect to sediment transport.

Analytical Prediction

Hallermeier (1977, 1978, 1981a, b, c) developed the first predictive formula for the DoC. Using laboratory tests and limited field data, he hypothesized two limit depths, d_l and d_i (Fig. 2). He defined the inshore limit depth, d_l , as the seaward limit of the *littoral zone*, where “intense bed activity (is) caused by extreme near-breaking waves and breaker-related currents” (Hallermeier 1981c, p. 258). Seaward of d_l , the deeper limit, only insignificant onshore–offshore transport by waves occurs. Between these two limits, is the shoal zone, a buffer region zone where expected waves have neither a strong nor a negligible effect on the sandy bed during a typical annual cycle of wave action.

Hallermeier (1978) suggested an analytical approximation, using linear wave theory for shoaling waves, to predict an *annual* value of d_l :

$$d_l = 2.28H_e - 68.5 \left(\frac{H_e^2}{gT_e^2} \right) \quad (1)$$

where d_l is the annual DoC below mean low water (MLW), H_e is the nonbreaking significant wave height that is exceeded 12 h per year (0.137% of the time), T_e is the associated wave period, and g the acceleration due to gravity.

According to Eq. 1, d_l is primarily dependent on wave height with an adjustment for wave steepness. Hallermeier (1978, p. 1501) proposed using the 12 h exceeded wave height because it allowed sufficient duration for “moderate adjustment towards profile equilibrium.” Equation 1 is based

Depth of Closure on Sandy Coasts, Fig. 2 Definition sketch showing limits d_i and d_b , where d_i is the maximum water depth for nearshore erosion by extreme (12 h per year) wave condition (From Hallermeier 1981c)

on quartz sand in salt water with a submerged density of $\gamma' = 1.6$ and a median diameter between 0.16 and 0.42 mm, which typifies conditions in the nearshore for many beaches. Because d_i was derived from linear wave theory for shoaling waves, d_i must be seaward of the influence of intense wave-induced nearshore circulation.

However, because of various factors, Hallermeier (1978, p. 1502) “proposed that the calculated d_i be used as a minimum estimate of profile close-out depth with respect to low (er) tide level.” Because tidal or wind-induced currents may increase wave-induced near-bed flow velocities, Hallermeier suggested using MLW as a reference level to obtain a conservative DoC. Although Hallermeier considered only an annual period, Stive et al. (1992) extended Eq. 1 to other time periods by defining H_e as the 12-h exceeded wave height over any time period.

Birkemeier (1985) used 2 years of profile data from Duck, North Carolina, to examine Eq. 1. He reasoned that since any storm could be the annual event, an event-dependent d_i could be computed for each storm. Taking this approach, he showed that the functional relationship proposed by Hallermeier appeared reasonable, but Eq. 1 overpredicted the observed DoC by about 25%. Nicholls et al. (1998) expanded on this analysis using 12 years of profile data to examine the parameters in Eq. 1. Using a depth change criteria of <6 cm between surveys as an indicator of the DoC, they confirmed that using the 12-h exceeded wave height and a datum of MLW provided a conservative estimate of the observed DoC (Fig. 3). They also examined the variation of the DoC with time and found that Eq. 1 became less capable at prediction as the time interval was increased beyond 4 years. They hypothesized that this indicates that, as the time interval increases, the DoC will be governed by other processes beside the highest wave height.

On eastern Lake Michigan, Hands (1983), using 9 years of profile surveys, determined that the closure depth was equal to twice the height of the 5-year return period wave height (H_5):

$$Z \simeq 2H_5 \quad (2)$$

Depth of Closure on Sandy Coasts, Fig. 3 Observed versus predicted DoC using Eq. 1 for erosional events measured in Duck, NC, USA (Modified from Nicholls et al. 1998). Except for a few cases of $d_i < 4$ m, Eq. 1 overpredicts, providing a conservative estimate of the actual observations

This relationship is similar to Eq. 1, being based on wave height. One requirement of both equations is that they assume sand-rich profiles and require knowledge of the near-breaking wave climate.

Empirical Prediction

The DoC can also be determined empirically by examining seafloor elevation changes measured by repetitive beach and nearshore surveys and identifying the depth at which changes become insignificant (see also Stauble et al. 1993; Grosskopf and Kraus 1994; Nicholls et al. 1998; Kraus et al. 1999). Since surveys integrate the impact of all processes acting on the profile, they inherently include the influence of storm and calm conditions along with important parameters not included in Eq. 1 such as grain size, sediment transport, and underlying geology.

Depth of Closure on Sandy Coasts, Fig. 4

Profile surveys and standard deviation of seafloor elevation at 74th Street, Ocean City, MD (Adapted from Stauble et al. 1993). Surveys conducted from 1988 to 1992. Large changes above the datum were caused by beach fill placement and storm erosion

Depth of Closure on Sandy Coasts, Fig. 5

Variation in short-term closure depth along the south shore of Long Island, NY, computed for four survey dates in 1995 and 1996 (Adapted from Morang et al. 1999). Zones indicate south shore barriers or regions

In order to identify at what depth changes become insignificant, Kraus and Harikai (1983) examined the standard deviation in depth change computed from a series of surveys, and defined closure as the depth where the standard deviation decreased markedly to a nearconstant value. They interpreted the landward region of this depth to be the active profile, where the seafloor was influenced by gravity waves and storm-driven water level changes. The offshore region, of

smaller and nearly constant standard deviation, was primarily influenced by lower frequency sediment-transporting processes such as shelf and oceanic currents (Stauble et al. 1993).

An example of how closure was determined empirically at Ocean City, MD, is shown in Fig. 4. A clear reduction in the standard deviation occurs at a depth of about 5.5–6 m below the National Geodetic Vertical Datum (NGVD) for the 13 surveys conducted over a period of 5 years. For the 5.6 km of

shoreline surveyed at Ocean City, the DoC ranged between 5.5 m and 7.6 m. This longshore variation may reflect complex nearshore bathymetry resulting from shore-attached linear shoals. A similar longshore variation in the DoC is shown in Fig. 5 for 110 south shore Long Island profile lines. Generally, the depth increases toward the east, with Rockaway Beach averaging 5 m below NGVD and the Montauk zone averaging 7.6 m. These values were based on four high-quality surveys collected between 1995 and 1996 (Morang et al. 1999). The depth increase toward the east corresponds to an eastward increase in wave energy and further reflects the wave height dependency of Eq. 1. These data also demonstrate that there can be considerable variation in DoC along an 80 km, relatively straight stretch of shore.

While survey data can be used to determine the DoC, surveys have several limitations that require careful consideration. Most importantly, a repetitive survey program should cover at least the time interval of interest with enough frequency to resolve the natural variation which occurs. In general, the longer the program, the more different conditions will be monitored and the more robust the closure depth determination will be. To resolve small changes in depth and in standard deviation, highly accurate surveys ($\pm 2\text{--}3$ cm) are required and profiles must extend offshore far enough to include the entire active shoreface. In the United States east coast, surveys to 10 m water depth are normally sufficient.

Application

Closure depth is used in a number of coastal engineering applications such as the placement of mounds of dredged material, beach fill, placement of ocean outfalls, and the calculation of sediment budgets. The time dependent nature of the active portion of the shoreface requires a coastal engineer to consider return period. The closure depth that accommodates the 100-year storm will be deeper than one for a 10-year storm. Therefore, a closure depth must be chosen in light of a project's engineering requirements and design life. For example, if a berm is to be built in deep water, where it will be immune from wave resuspension, what is the minimum depth at which it should be placed? This is an important question because of the high costs of transporting and disposing material at sea. It would be tempting to use a safe criterion such as the 100- or 500-year storm, but excessive costs may force the project engineer to consider a shallower site that may be stable only for shorter return period events. The prediction techniques described above allow for both the determination of a closure depth and for the consequences of picking a shallower or deeper depth to be quantified.

Most research into the closure depth have been carried out on sandy beaches with a thick sand layer in wave-dominated

environments. Therefore, assumptions behind the concept hold best on open coasts far from structures and inlets and may be less valid for beaches where the morphology is largely controlled by underlying geology, for example, where the active sand is only a veneer above rock or clay. Also, little is known about the DoC for coasts where most sediment is moved by unidirectional currents, such as rivers and tidal channels or where there is long-term net loss of sediment.

Depth of Disturbance

John P. Ahrens
Mason Neck, VA, USA

Definition

Depth of disturbance, is the depth to which wave action can be expected to disturb the underlying bottom sediment. Sources of disturbance other than wind waves are not discussed. The sediment is considered to be unconsolidated particles in the sand size range.

Background

The approach adopted is to develop analytic expressions to estimate the depth of disturbance through the use of the velocity ratio,

$$U = u_{-h \max} / u_{\text{crit}}, \quad (1)$$

Where $u_{-h \max}$ is the maximum near-bottom orbital velocity of the wave and u_{crit} is the critical velocity required to initiate sediment movement under the wave. If U is greater than 1.0, then movement of the sediment would be expected; if U is less than 1.0, sediment movement would not be expected. Ahrens and Hands (1998) found the parameter U very effective for distinguishing between beach erosion/accretion events. For shallow water conditions, $u_{-h \max}$ will be estimated using Stream Function Wave Theory (SFWT), (Dean 1974). For deep water, $u_{-h \max}$ will be estimated using linear wave theory. The critical velocity will be estimated using the relation,

$$u_{\text{crit}} = \sqrt[3]{(8\Delta g d)}, \quad \text{for } 0.0625 \leq d \leq 2.0 \text{ mm}, \quad (2)$$

where g is the acceleration of gravity, d is the sediment grain diameter, and $\Delta = (\rho_s - \rho)/\rho$, where ρ_s is the density of the sediment and ρ is the density of water; Eq. 2 is based on research by Hallermeier (1980).

Concepts and Development

It is convenient to approximate the dimensionless near-bottom velocity as a function of relative depth, that is, $u_{-h \max} T/H = f(h/L_0) < \text{check}>$, where H is the wave height, h is the water depth, and L_0 is the deep water wave length given by $L_0 = gT^2/2\pi$, where T is the wave period. The general functional form used is:

$$f_i(h/L_0) = \exp[C_0 + C_1(h/L_0)](h/L_0)^{C_2}, \quad (3)$$

where C_0 , C_1 , and C_2 are dimensionless coefficients developed from regression analysis. Table 1 gives the values of the coefficients for the two wave theories and ranges of relative depth.

The breaker height, H_b , consistent with SFWT, can be estimated quite accurately as a function of relative depth using the relation,

$$H_b = 0.171 L_0 \tan h[0.73(2\pi h/L_0)], \quad (4)$$

(Ahrens and Hands 1998). In general, the wave height can scaled as a fraction of H_b , that is, $H/H_b/a$, where 1.0 or 4.0 in this article. When the above relations are brought together, the following equation is obtained,

$$U = 0.171 \tan h[0.73(2\pi h/L_0)] f_i(h/L_0) / a [16\pi\Delta(d/L_0)]^{1/2}, \quad (5)$$

where $f(h/L_0)$ can be any of the three functions indicated by Eq. 3 and Table 1. Equation 5 shows that U is a function of three variables, h/L_0 , d/L_0 , and Δ , however, typically Δ only varies over a small range. To obtain a visual impression of the influence h/L_0 , d/L_0 , on the depth of disturbance, U is set equal to 1.0 and $\Delta = 1.6$ to produce Fig. 1.

Two roughly parallel curves arch across Fig. 1 the upper curve is associated with H_b and the lower curve with $H_b/4$. There is a slight discontinuity in the H_b curve because linear wave theory and SFWT are not quite consistent at the transition depth, h/L_0 0.2. In Fig. 1 the area of primary interest is

Depth of Disturbance, Table 1 Coefficients used to estimate dimensionless bottom velocities

Function	Wave theory	Wave height	Relative depth range	Coefficients		
				C_0	C	C_2
f	SFWT	H_b	0.002 h/L_0 0.2	−0.227	−2.078	−0.600
f	SFWT	$H_b/4$	0.002 h/L_0 0.2	0.0835	−2.819	−0.601
f	Linear	All	0.2 h/L_0 2.0	1.930	−6.368	0.103

Depth of Disturbance,

Fig. 1 Depth of disturbance plane, relative grain size, $\sqrt[3]{(d/L_0)}$, versus relative depth, h/L_0

outlined by three heavy, straight lines. The maximum and minimum relative grain sizes are based on the grain size range of $0.0625 \leq d \leq 2.0$ mm and the range of wave periods considered, $2.0 \leq T \leq 20.0$ s. The “ h 100 cm limit” line indicates where the upper limit is 100 cm deep; above this line depths are less than 100 cm and the scale of the wave action is small.

Summary

Figure 1 is a map of the depth of disturbance plane for two wave heights; one equal to the breaker limit, H_b , and the other one quarter the breaker limit. On the right side of the figure, in deep water, is a region of no disturbance. Next to the no disturbance region is a region which is disturbed by large waves, that is, $H_b/4 \leq H \leq H_b$. Beneath this region is a region considerably disturbed by large waves. Above the h 100 cm limit is a region disturbed by relatively large waves and surprisingly a region of no disturbance. However, above the $h = 100$ cm limit wave conditions are small since the water depth is less than 100 cm.

Desalination

Bénédicte Cherbuy¹ and Jean-Christophe Aznar²

¹CEFE-CNRS, Montpellier, France

²Desmid-CNRS, Arles, France

Water is a valuable natural resource, necessary for domestic, industrial, and agricultural activities. Because of the worldwide population growth, economic development, and erroneous management choices, humanity is nowadays facing an increasing scarcity of satisfactory quality water. This threat is stronger in the arid and semiarid areas (Kulga and Adanali 1990) but could extend to other regions in the context of a global climatic change which could modify the precipitation patterns at a worldwide scale (Pearce 1996). The possibility of utilizing saline underground and

seawaters, by removing soluble salts from water by desalination technology, is therefore considered today with an increasing attention.

Major Processes of Desalination

Important research programs had been put in place by the 1980s. Taking into account industrial requirements, three major processes have emerged. Distillation is the older method. Saline water is evaporated partially, leaving the salts behind. The desalinated vapor is then condensed in a separate container. Electrodialysis is based on the mobility of ions in an electrolyte submitted to an electric field. Membranes are placed between a pair of electrodes. Negative ions (anions) migrate toward the anode and positive ions (cations) toward the cathode, creating concentrated and diluted solutions between the alternating membranes. Reverse osmosis is the more recent, and today the most common, technology. The natural osmotic flow is reversed by applying pressure that forces the salt water through a membrane, permeable only for pure water.

A number of other methods may prove valuable under special circumstances or with further development. Freezing is based on the principle that water excludes ions when it crystallizes to ice. In the ion-exchange process, water passes through a bed of specially treated synthetic resin which extracts ions from the solution and replaces them with ions that form water.

Costs of Desalination

Total costs of desalination include initial technological investment and energy costs. The minimum energy requirement represents the energy necessary for obtaining freshwater from saline water in the case of an ideal reversible thermodynamic transformation (Nebbia 1968). In practice, the existing desalination methods consume an amount of energy which is at least 70 times greater than this theoretical minimum (Pearce 1996). This energy consumption is one of the causes for the high costs of desalination. The selection of an appropriate method depends thus on these economical considerations. Distillation is the more expensive process because of the great quantities of fuel required to vaporize salt water. Electrodialysis and reverse osmosis, which can desalt water much more economically, have therefore replaced distillation for the desalination of brackish water. Because of the high cost of membrane replacement however, these two processes are less suitable for desalinating seawater. Technological advancement has also allowed some reduction in the total desalination cost, by improving energy efficiency (multiflash distillation or hybrid systems), by facilitating

transfer processes, by energy recycling (process of cogeneration) or by using solar energy.

Ecological Impacts of Desalination

Wastewater effluents may have potentially adverse effects on the environment. They present excessive salt concentrations, increased temperatures, and increased turbidity levels and can be charged with chemicals, organics, and metals. In addition, distillation entails an oxygen depletion. These problems can be avoided by treating the effluents before releasing them in the environment but this constraint again increases the cost of desalination.

Conclusion

Desalination offers a nearly unlimited potential of freshwater, particularly in coastal areas. However, this technology is still not extensively developed, because the cost of freshwater production remains a problem. Some countries, which have opted for large-scale desalination, are now searching for more economical solutions (Nativ 1988). Desalination is essentially utilized to solve survival problems and development of arid and semiarid areas. The use of desalinated water in agriculture is by far less important, particularly because irrigation does not need high water quality (Rhoades et al. 1992). The limits of salinity are generally two to five times those tolerated for industrial and domestic water (Nebbia 1968). In the case of salinity sensitive crops such as citrus, however, partial desalination by mixing a part of desalinated water to saline underground water, is an interesting solution (Matz 1965). Because of industrial research and because of the rise in cost for conventionally treated water, desalination turns out to be more and more feasible, economic, and reliable and its importance is expected to increase in the future years. However, even if the problem of freshwater rarefaction can be, in the more or less long-term, technologically solved, we must wonder if an increasing demand for freshwater is compatible with the current will of preserving ecosystems and biodiversity. Excessive water utilization has serious consequences on the function of precarious ecosystems like wetlands (Pearce 1996). Better management options, centered on conservation and economy of resources constitutes a cheaper, more durable, and more ecological solution in face of water scarcity.

Desert Coasts

Rodman E. Snead
Department of Geography, University of New Mexico,
Albuquerque, NM, USA

Very great environmental differences exist among the coastal deserts of the world. On an overall worldwide basis climate is the best criteria for subdivisions. Climatically, the coastal deserts fall into four principal types which can be called hot, warm, cool, and cold (Figs 1 and 2).

Hot Desert Coasts

The hot coastal deserts cover the largest areas (Fig. 3). Their approximate length is 10,000 miles (16,000 km). This truly tropical hot climate exists only along the southern half of the Red Sea and adjacent coasts of Arabia and the Somaliland horn of Africa (Figs. 4, 5, 6, and 7). The equatorward sections are warm even in winter with winter temperatures getting above 80°F (25°C) in the heat of the day and only dropping to 70°F (21°C) in the coolest part of the night. The poleward or subtropical type prevails along the Persian Gulf and the Indian Ocean margins of northwestern India, Pakistan, and Iran the northern Red Sea; the Gulf of California, and northwestern Australia.

Most of the hot coastal deserts have relatively little cloud or fog but very high solar radiation. Owing to shallow sill restrictions at the mouths of the Red Sea and the Persian Gulf the water does not mix freely with the colder water of the open

ocean, and as a result the water temperature is higher by several degrees. In summer the surface temperature in the southern part of the Red Sea is above 86°F (30°C) and in winter over 77°F (25°C). The Persian Gulf is hotter than the Red Sea in summer, but much cooler than the Red Sea in winter.

Warm Desert Coasts

The second type of coastal desert can be called warm rather than hot because summers are less hot, with mean temperatures, even in the warmest month being less than 86°F (30°C). The longest single stretch of this climate, about 1,600 miles (2,600 km), is along the Mediterranean Sea, where the Sahara Desert reaches the coast (Figs. 8 and 9). Though occasional short rainstorms occur during the winter season, most of the days are bright, mild, and sunny. It might be noted that the climate plus the nearness to densely populated Europe, makes this one of the important winter seaside resort areas of all coastal deserts.

Warm coastal desert climates along exist along the west and south end of Baja California, Mexico (Fig. 12), with winter rainfall in the north, summer showers in the south, and non-seasonal very slight rainfall in the center. All the other west-coast deserts of the world also have warm climates in their equatorward positions, such as Angola, Maruritania, Peru, and Australia (Figs. 10, 11, 13, and 16). Like the southern end of Baja California (Fig. 12), these coastal areas all have their rainy season, such as that occurring, in summer, which is in harmony with their marginal tropical locations. A small but distinct area of this type of warm desert occurs at the southwestern coast of Madagascar (Fig. 11). Tourism is developing in some of these areas, especially the southern end of California where visitors from the United States and mainland Mexico come by air, sea, or some by road. Near their equatorial ends, these west-coast warm deserts are relatively free from cloud or fog. Toward their polar ends, especially in Peru, southwestern Africa, and Baja California (Figs. 11, 12, and 13), there is frequent low cloud or fog in summer, as the warm deserts merge into the cool deserts.

A particular tourist and biological resource of this part of Baja California is the gray whale, which travels thousands of miles, from the North Pacific to breed in Scammon's Lagoon, at 27°45'N latitude.

Cool Desert Coasts

Type 3, the cool desert coasts from the poleward portion of all five westdesert coasts. They occur nowhere else if the shores of the Great Bight of Australia (Fig. 17) is considered an extension of the west-coast desert. The longest stretches of

Desert Coasts, Fig. 1 Coastal desert types in Asia and Africa. (Adapted from Meigs 1966)

this cool desert coast are along the Peru-Chile coast, 2,100 miles (3,400 km) (Fig. 14).

Nowhere else on earth is there a coastal desert of such intense aridity which spans so many degrees of latitude as the Chilean-Peruvian desert. The extreme dryness is all the more interesting when one considers that no part of this desert is far from a tropical ocean, for at a maximum it is never more than a few score miles (kilometers) in width, and the fact that the atmospheric humidity is high is attested to by the presence of a great deal of low stratus cloud, fog, drizzle, and heavy dew. Still it seldom rains. Obviously, the dynamic controls making for drought are amazingly well-developed.

Among the climatic anomalies of the Chilean-Peruvian desert two are particularly notable, (1) the unusual intensity of the dryness in conjunction with its latitudinal extensiveness and the abruptness with which it ends on both the north and south, so that a transitional steppe climate is only meagerly developed, and (2) the brief periods of heavy rainfall and high temperatures which vary occasionally affect mainly the northern parts of this desert area, this temporarily revolutionizing its weather and changing it to wet tropical conditions. In

addition, the Peruvian-Chilean desert has uncommonly well developed those special features of climate which are peculiar to dry western littorals bordered by cool currents. Such as relatively low annual temperatures, small annual and daily ranges of temperature, and the existence of much low stratus fog, cloud, and even drizzle.

Other locations where Type 3, the cool desert coasts, occur are the west coast of Namibia and South Africa, 1,200 miles in length. (2,000 km) (Fig. 11), while smaller sections include northern western Sahara and southern Morocco (Fig. 10). Baja California has a short segment just south of the California border (Fig. 12). These are foggy deserts with fog forming over the cool waters offshore and moving onto the adjacent land either as "high fog or low cloud," or at times directly along the ground. To the cooling effect of the cold water onshore can be added the reduction of solar radiation by the fog blanket. It can also be added that there are regional differences in the season of maximum fog. Along the Chile-Peru coast the season of great fog is in winter; while along the Baja California and northwest Africa coasts there is a summer maximum of the fog. Solar radiations is also affected by high

Desert Coasts, Fig. 2 Coastal desert climatic types. (Adapted from Meigs 1966)

clouds associated with the seasonal rainfall regimes of the neighboring human-occupied areas: winter in most of the cool desert climates, while summer occurs in the main part of the Peruvian coast. However, it can be said, the deserts of the coast provide attractive relief for people from the hot interior valleys or deserts. It might be added that the special circumstances of cool to cold ocean waters offshore has resulted in great fishing grounds.

Cold Desert Coasts

The coldest coastal desert of all, Type 4 of the classification, occurs along the southeast coast of Patagonian Argentina (Fig. 15). Here a cool to cold ocean current reinforces the

dry rain-shadow effect of the Andes on the westerly storms that normally prevail in these latitudes. This desert extends to more than 50°S latitude, which is farther poleward than any other coastal desert in the world. The mean temperature of the coldest month is below 50°F (10°C), and the temperature of the warmest month is between 50° and 72°F (10° and 22°C). With such limited heat only the hardiest vegetation and crops grow in this region. Other resources must provide the principle economic basis for settlement.

This account considers only the connecting, not even the oceans. The inland lakes and seas are not considered, not even the large Caspian Sea. This sea has a climate quite different from those of other coastal deserts. Most of its climate (except along the southwest borders) is continental: colder in winter than the coldest of the coastal deserts (Type 4), with averages

Desert Coasts, Fig. 3 Kathiawar-Makran coastal deserts. (Adapted from Meigs 1966)

below freezing; and ranging with the warmest deserts (Type 2) (Figs 16 and 17) in summer. The sea affects the temperature of the land immediately adjacent to it, as occurs with other coastal deserts.

Coastal Desert Environments

A great variety of landscapes and landforms occur along desert coasts, in fact nearly every type of landform. Desert and semidesert coastal lands make up about 20–25% of all such world regions. Coastal dunes and desert plains predominate but long stretches have steep escarpments or plateaus which rise directly from the sea. In places such as the Makran coast of Pakistan, quite recent uplifted terraces predominate.

The source of sand for desert coasts comes mainly from the sand left on beaches which is moved inland by changing tides and waves plus coastal winds. Another major way for sand to reach desert coasts is by intermittent rivers and streams which carry the sand in short flash floods. The sand is either carried into the sea and then moved by waves and currents along the beaches or picked up by winds in river beds and moved to coastal dunes. There is a changing balance between wind transport of sand and by running water in river beds.

Most aeolian bodies occur in basins in the desert. The Pleistocene probably saw periods of more intense fluvial

erosion than the present. Many coastal ergs are fashioned out of deposits of Pleistocene or late Tertiary alluvium.

Clay dunes are perhaps surprisingly better authenticated than silt dunes and are more obviously dune like. They have been reported from the Gulf of Texas, northern Algeria, Australia, and the Senegal Delta.

Although it is not difficult to recognize a desert, opinions vary as to the physical features of the environment that should be used as criteria for defining a desert climate. Rainfall must obviously be taken into account, and desert conditions usually prevail in tropical regions when the average rainfall is under 5 in. (127 mm), with semidesert conditions occurring when the average rainfall is over 5 in. (127 mm) but under 15 in. (381 mm). But such figures can be only approximate, because what matters is not only the amount but the effectiveness of rain; and the effectiveness of rain depends on its seasonal occurrence, its rate of evaporation, and the nature of the soil (Cloudsley-Thompson 1975, p. 8).

The aridity of coastal deserts that results mainly from a lack of rain is often due to the way in which the atmosphere circulates, particularly in its lower layers, and this partly explains the geographical distribution of the world's coastal deserts: near latitudes 30°N and S, the direction of the winds tend to vary, and the air sinks. When this happens, it is warmed by the hot ground, and clouds are dispersed. At the same time, high-pressure belts that

Desert Coasts, Fig 4 Coastal deserts of the Persian Gulf area. (Adapted from Meigs 1966)

Desert Coasts, Fig. 5 Coastal deserts of southeastern Arabia. (Adapted from Meigs 1966)

separate the polar westerly winds and the tropical easterlies occur near these latitudes. Consequently, the disturbances associated with low pressure, which usually cause rain, are rare. Then, too, there are some local factors that quite often

result in low rainfall. These include the rain-shadow effects of mountain ranges, which cause the air to drop all its moisture as it crosses them. For example, the Patagonian desert including the Argentina coast, is the result of both

Desert Coasts, Fig. 6 Coastal deserts around the Red Sea. (Adapted from Meigs 1966)

the rain-shadow effect of the Andes Mountains, which block the path of the westerlies, and the cool Falklands current alongshore.

Desert Coastal Vegetation

Most desert coasts support a *xerophytic* type of scrub vegetation which grows sparsely in most areas. A few scattered

trees, mostly the acacia type in tropical coastal deserts, can be found. In years with more than 8 in. (200 mm) of rainfall, a thick layer of grasses, herbs, and shrubs covers the ground. Climate is the major determinant of vegetation types, and rainfall is much more significant than temperature, however the amount of salt comes into play. In general, it can be said that along most desert coasts many of the shrubs are woody and stunted being about 12 in. (300 mm) high with round cushion-like out-lines. With bleached stems and few leaves

Desert Coasts, Fig. 7 Coastal deserts of the Somali Republic. (Adapted from Meigs 1966)

many look like skeletons of plants. A few annuals begin sprouting when warmer days occur. Although the number of families is large in most cases the number of species is small.

Again, speaking generally, the first dunes behind the back-shore differ in vegetation from the inland dunes. The difference is due mainly to high salinity and a high water table which often is only 0.5–4.0 ft (0.15–1.2 m) below the surface.

Natural and human factors disturb desert coastal vegetation and lead to temporary changes in plant cover. Disturbed areas result from such natural causes as varying moisture, wind and soil conditions, and destruction by sudden floods. Human activities along the coast which disturb plant successions include the clearing or destruction of the original

vegetation for purposes of cultivation, fuel, fodder, and building material. Animal grazing is the most destructive factor.

Several desert coasts have unusual vegetation types. For example, the Namib coast has vegetation that lives off of fog; both the Baja desert coast and the Galapagos Islands have unusual vegetation probably because, for a long period of time, they were so isolated, new species of plants developed.

Animals and Plants

It is not easy for plants and animals to survive in desert coastal regions where extremes of drought and flood, of

Desert Coasts, Fig. 8 Coastal deserts along the Mediterranean Sea. (Adapted from Meigs 1966)

Desert Coasts, Fig. 9 Coastal deserts of the Nile Delta. (Adapted from Meigs 1966)

Desert Coasts, Fig. 10 Atlantic-Saharan coastal desert. (Adapted from Meigs 1966)

Desert Coasts, Fig. 11 Coastal deserts of southwestern Africa. (Adapted from Meigs 1966)

erratic rainfall, or no rainfall at all, only fog and dew, can occur. Therefore, it is not surprising that animals and plants have adaptations that are correspondingly extreme. Desert animals usually run faster than their relatives in temperate regions. Venomous forms are more poisonous than their allies beyond the desert's fringe. Spiny plants are more prickly, and distasteful ones more unpleasant, than anywhere else.

Most desert and semidesert coastal regions support some degree of vegetation. The smallest amount of plant life exists in areas of rocky *hammada* and cracking clay; but plants can grow even in such soil whenever it is traversed by wadis. And sandy desert usually supports a flora of some kind, except on the dunes, which tend to stay quite bare. Many plants, such as annual grasses and other small herbs, evade the more extreme desert conditions by completing their life cycle during the

Desert Coasts, Fig. 12 Coastal deserts of western Mexico and Baja California. (Adapted from Meigs 1966)

short rainy season and passing the remainder of the year lying dormant as fruits or seeds in the soil. Dry seeds can often survive high temperatures without losing their ability to germinate later under more favorable conditions (Cloudsley-Thompson 1975, p. 26).

Most plants of arid regions have evolved mechanisms not so much of drought tolerance as of resistance to drought. They fight the battle against water loss in a number of ways, often combining different protective devices within a single plant. One means of retaining moisture is to have leaf surfaces coated with fatty substances and resins; these making it harder for water vapor to escape. Other structural adaptations to drought include the presence of dense, hairy coverings (which again keep moisture from escaping) or of pores sunk deep into the leaf tissue so that the dry wind cannot blow directly into them.

Smaller and fewer leaves also help resistance to water loss. And – perhaps most important of all devices – a number of desert plants have developed internal tissues for storing water over long periods of time and for giving increased mechanical support to the bloated, water-filled organism after a heavy rainfall. Such plants (among them the cacti) are known as *succulents* (Cloudsley-Thompson 1975, p. 29).

Some plants can survive on moisture from the air; and at night, with the drop in temperature, dew condenses on their leaves and stems and runs down into the soil around the roots. The welwitschia of the Namib Desert in southwestern Africa is such a plant. It bears two curling leaves, split longitudinally into strips, on which dew condenses, providing water for the shallow roots. The ability of vegetation such as the welwitschia to absorb moisture from the night air, even when dew does not

Desert Coasts, Fig. 13 Peruvian coastal deserts. (Adapted from Meigs 1966)

form, can make vitally needed water available for snails, insects, and other small animals of the desert.

Desert vegetation is not entirely ephemeral. There are many plants that habitually grow where evaporation stress is high and water supply low, and that do not need to evade extreme coastal desert conditions. Such plants, all of which show characteristic adaptations to their environment are termed *xerophytes* (from the Greek words meaning “dry” and “plant”). Among them are trees, perennial grasses, and species that develop bulbs, corms, or tubers. Some xerophytes are characterized by the ability to survive long periods of drought and dehydration of the tissues without suffering injury. They are extremely resistant to wilting, and a few species can lose up to 25% of their water content before they begin to wilt.

Another characteristic feature of most desert coastal plants is that they possess painfully sharp thorns and spikes. The

probable function of these is to afford protection against browsing and grazing animals. Many contain poisonous or irritant latex. Other secrete resins or tannins in the bark or levels; the pods of some contain strong purgatives. All such devices tend to make the desert plants unpalatable to animals (Cloudsley-Thompson 1975, pp. 27–30).

Case Study of the Pakistan–Iran Climate Regime

The Pakistan part of this desert coastal type is interesting because it is an area of transition between the Indian summer monsoon system to the east, and the winter cyclonic system of southwest Asia to the west. As a transition area, it receives scanty, unreliable rainfall, averaging less than 10 in. (250 mm) per year from several storm types. Six main weather patterns cross the region, the large subtropical

Desert Coasts, Fig. 14 The Atacama desert. (Adapted from Meigs 1966)

anticyclonic high-pressure cell which predominates most of the year; western depressions originating over the Mediterranean Sea; a modified monsoon pattern; eastern depressions originating over the Bay of Bengal and central India and local thunderstorms and dust storms.

The seasonal division of rainfall for southern Pakistan is shown in Fig. 3. Nearly all of Sind and the eastern part of Baluchistan, particularly the Las Bela area, have a pronounced summer monsoon maximum coming in June, July,

Desert Coasts, Fig. 15 Coastal deserts of Patagonia. (Adapted from Meigs 1966)

and August. This line conforms to the eastern slopes of the Kirthar and Sulaiman mountain ranges which act as a barrier to storms from the east. Iran and the western part of Baluchistan have a winter maximum coming from November to March with very little summer precipitation. Central Baluchistan is a region having both winter and summer rainfall with a slight winter maximum, while a thin band in eastern Baluchistan is an area having both winter and summer rainfall, but with a slight summer maximum.

Developed Coasts

Nancy L. Jackson¹ and Karl F. Nordstrom²

¹Department of Chemistry and Environmental Science, New Jersey Institute of Technology, University Heights, Newark, NJ, USA

²Department of Marine and Coastal Sciences, Rutgers University, New Brunswick, NJ, USA

Definition

The term “developed coast” often implies a natural system altered by human action.

The type, frequency, and magnitude of alterations are influenced by social and economic value humans place on the resource. Today, developed coasts are modified and physically maintained to enhance navigation, recreation, and protection of settlements. Human modification of the coast has resulted in changes to the dimensions and locations of coastal landforms and the spatial and temporal scales of cycles of erosion and accretion. Globally, human presence on the coast dates back tens or even hundreds of thousands of years, with some of the earliest documentation on the Mediterranean coast, where deforestation and overgrazing increased the quantity of sediment delivered (Nordstrom 2000). Channelization, diversion, and impoundment of water resources had the opposite effect on the coastal sediment budget; levees and dams decreased sediment delivery from river sources, with the most conspicuous effects occurring in the twentieth century. Grazing initiated dune migration when practiced on the coast.

Direct human alterations to the coast increased in scale with increased occupancy and technological advances associated with the availability of steam power (Marsh 1885) and then the internal combustion engine that further enabled the creation and removal of landforms and redistribution of sediment. Pronounced changes to the landscape occurred about the mid-nineteenth century. Marinas and harbors were constructed, and inlets were regulated through sediment dredging and jetty construction.

Coastal tourism and resort development, beginning in earnest during the second half of the nineteenth century, resulted in further alteration of the coast. Seasonal house construction and infrastructure development (transport and utilities) along the coast resulted in elimination of dunes, while marshes were eliminated by dredging and filling to create navigation channels, marinas, and substrate for structures. Development near the shoreline increased vulnerability to wave attack and flooding during storms, requiring shore protection. Large-scale shore protection efforts, primarily groins and seawalls, were initiated in the late eighteenth

century in Europe and in the mid-nineteenth century in the United States (Nordstrom 2000). Use of these structures, referred to as hard stabilization or armoring, increased with increased construction of buildings and support infrastructures. Considerable attention is now placed on making protection structures more compatible with the geomorphic and ecologic environment where they are constructed (Nordstrom 2014). Beach nourishment (placement of sediment on the beach and nearshore profile from an external source) was first used in the early twentieth century and became popular in the second half of the century. Identified as soft stabilization, nourishment is now the preferred alternative to protect development from storm erosion and flooding in locations where suitable sediment sources are available (National Research Council 2014). Introduction of large volumes of sediment to developed shorelines that previously had a sediment deficit has created opportunities for the restoration of many geomorphic features lost to human development.

Characteristic Landforms

Many of the characteristic landforms found on developed coasts differ from their natural counterparts in size, location, and spatial and temporal scales of change but are identified using similar terminology. The attributes of landforms found on developed coasts can be the intended or unintended outcome of their modification for human use. Over time, assemblages of human-altered landforms may be accepted as natural and require further human modification to maintain their resource value (van der Meulen et al. 1989).

Beaches on developed coasts are generally narrow, because of reduced sediment supply, but nourishment can displace the shoreline seaward and create a beach that is initially wider than a natural beach. Nourished beaches, when designed for shore protection, are often higher in elevation than their natural counterparts, but beaches downdrift of shore protection structures such as groins will be lower. Most direct human modifications to beaches are intended to reduce shoreline mobility over the long term, although mobility may be higher than expected immediately after modifications such as inlet creation or closure or beach nourishment. The characteristics of sediment found on nourished beaches are dependent on the source, which may be derived from offshore, including inlets.

The location and size of dunes are controlled by direct human actions, such as bulldozing and placement of sand fences, and indirect actions through the passive influence of shore protection structures that trap wind-blown sediment (Jackson and Nordstrom 2011). Human modification by fencing, vegetation planting, or mechanical grading creates forms designed to optimize human values such as shore protection,

views of the sea, or ecological enhancement. Small incipient dunes are often lacking because beach wrack is eliminated by beach cleaning operations. Secondary dunes are often lacking because that zone is occupied by human structures. Sedimentary characteristics and internal structure of dunes that form around human structures by aeolian processes can be similar to natural dunes. Dunes created by bulldozing have poorly defined internal structure and contain sediment that may be too coarse or too fine to be transported by local winds. Dunes created by humans are often less mobile than those created by aeolian processes alone because fencing or buildings constructed close to the shoreline restrict migration.

Construction of shore protection structures, introduction of beach nourishment, and management decisions of communities can result in pronounced changes to beach and dune ecosystems (Dugan et al. 2008; Buleri and Chapman 2010). The presence of shore parallel structures such as seawalls and revetments can reduce backshore widths, alter abundance and diversity of species in the intertidal zone, and reduce availability of foraging areas (Dugan et al. 2008), but shore protection structures that incorporate ecological components can increase ecological value of hard stabilization (Buleri and Chapman 2010). Beach nourishment can also have negative effects on both flora and fauna, but adverse effects can be partially mitigated by matching natural and native sediments and timing nourishment during low beach use by birds and other organisms (Speybroeck et al. 2006).

Assessing Change

Landforms on developed coasts respond to energy inputs according to the same laws as natural landforms, but the spatial and temporal scale of change can differ because of human action (Nordstrom 2000). Post-storm recovery of landforms on developed coasts is impeded by houses and infrastructures, but recovery by human modifications can occur rapidly. Closure of inlets created during storms, bulldozing of sediments onto the back beach from overwash deposits on streets, and reconstruction of dunes using sand fences or earth-moving equipment rapidly restore the coast to the pre-storm landscape to achieve social and economic resource values. Human alterations to the coast may be more dramatic in the future in response to the increased hazards caused by sea level rise (Nichols and Cazenave 2010).

Shoreline changes and economically driven human interventions are becoming mutually linked, requiring knowledge of societal action across a range of scales, quantification of anthropogenic effects through time, and communication between scientists and managers (Lazarus et al. 2016). While geomorphology has a strong influence on shoreline change, human actions can be a greater influence on change

along developed coasts (Hapke et al. 2013). Human action can be considered either external to or a part of the natural system (Phillips 1991). As an external influence, human action can be considered an overlay or aberration to a natural coastal system. Human action may now have to be considered an integral process, requiring a better understanding of the functioning of the developed coast and ways to manage it to achieve both natural and human resource values (Nordstrom 2000).

Summary

The morphology of developed coasts is shaped by both natural and human processes. Human alterations of these systems using shore protection structures and beach nourishment have eliminated or changed the dimensions of beaches and dunes and their ecological function. Better understanding of the coupling of human and natural processes on developed coasts can lead to increasing natural and resource values and future management.

Dikes

Pieter G. E. F. Augustinus

Department of Physical Geography, University of Utrecht, Utrecht, The Netherlands

Introduction

Dikes, especially sea dikes, are coastal constructions build to avoid flooding. The risk of flooding is detrimental to the safety of people and economic, cultural, and ecological values. This aspect has been of great importance since people first thought about defending their dwellings against flood hazards. In the distant past, dwelling mounts were built to protect families or small communities from the sea. They are known from several low-lying coastal areas in the world, for example, from the North coast of Germany and the adjacent Dutch coast, where they have been occupied ever since 2500 BP, as well as from the chenier coast of Suriname, where they date back to 1800 BP.

Population increase urged to a more active method of flood prevention. The people started to construct dikes to keep the water out of whole regions, thus protecting lives and properties against the sea. In the Netherlands, dikes have been built as a community activity from about AD 1100. Ever since, coastal defense has become more and more an engineering activity. Presently, the design criteria for sea dike construction are determined by three important groups of aspects: hydraulic, subsurface, and construction. The first two groups mainly determine the required height and strength of the dike. The last group of aspects is particularly important for the dike's duration of life. Details about the various aspects are given by U.S. Army Corps of Engineers (1984).

Hydraulic Aspects

Hydraulic factors influencing the marine water level at small temporal scales are the tidal range, wave height, wave run-up, and the setup of the water level due to wind conditions. Because dikes have to be calculated for extreme water

levels, especially a coincidence of extreme conditions of these factors are at stake, for example, high-water spring tide and wave characteristics and setup of the water level during storms. For the establishment of extreme water levels, high-water exceedence frequency curves are used. This method is based on the finding of a systematic relation between the height of a flood-tide level and the number of times this specific level occurs in a century. Extrapolation of the high-water exceedence frequency line enables a probability calculation for the chance that an extreme high-water level, not observed before, may occur. Moreover, the effects of long-term changes in sea level and storm frequency must be taken into consideration.

The final height of a sea dike is determined by the degree of risk of flooding, within the applied economic constraints, the community is willing to accept. In the Netherlands, for instance, the sea defense system is at “Delta height.” However, for the distinguished coastal sections of the Dutch coast this “Delta height” has different values. For the uninterrupted West-coast, which protects the most densely populated and economic heart of the country, the minimum height of the dunes and dikes is determined by a water level exceedence chance of 1 in 10,000 years. For most of the barrier islands in the north of the country the “Delta height” corresponds with a high-water exceedence chance of 1 in 2,000 years.

Subsurface Aspects

Subsurface aspects like subsidence and tectonic movements codetermine the behavior of the sea level. The Netherlands, for instance, are suffering from a relative rise in sea level, which is the combination of the eustatic sea-level rise and the subsidence of the land (Jelgersma 1961). Subsidence in this case is mainly due to the isostatic rebound after the last glaciation and the dewatering of the peaty subsoil in the coastal area for agricultural reasons, resulting in compaction. Especially in the past, this drainage has contributed to the general subsidence. At the same time, the central part of the Dutch coast is influenced by a graben system.

In the decision-making of the final height of a sea dike, the compaction of the subsoil due to the weight of the overlying dike body has also to be considered, as well as some compaction in the dike body itself.

The composition of the subsoil is relevant with regard to groundwater flow. A dike is meant to be impermeable for water. However, groundwater can be pressed to flow through the subsoil underneath a dike, due to a difference in hydrostatic pressure on both sides of the dike. The flow velocity depends on the volume of the overhead and on the permeability of the subsoil. This seepage causes saltwater intrusion landward of the dike. In case the currents are sufficiently

strong to erode the underlying sediment, this process affects the stability of the dike and ultimately may result in the collapse of the dike.

Construction Aspects

The construction of a dike requires building material. In the past, the preferably clayey material was locally dug. Nowadays, however, dikes usually have a sand nucleus, covered by clay to make it impermeable. Suitable clay usually is scarce, whereas sand occurs in large quantities. The advantage of this method is that sand not necessarily needs to be transported on a truck, but can be supplied in suspension by pipeline.

Because of the difference in hydrographic pressure on both sides of a dike, a groundwater table is formed in the sandy dike body. Although the clay cover has to be impermeable for seawater, it must simultaneously be able to let an excess of water from inside the dike through.

Generally, dikes have a delta form. To reduce the effect of wave runup, the slope of the seaward bank of a dike has to be small. On the contrary, the width of a dike increases in that case. A balance has to be found between cost and safety.

In the flood disaster in the Netherlands in 1953, the effect of overtopping water on the landward side of the dikes appeared to be the most important cause of dike failure. In order to reduce the effects of overtopping water, for example, the penetration of water into the center of the dike body, various degrees of unevenness can be applied.

To avoid erosion of the banks and undermining of the dike body revetments are applied. Usually these revetments are provided with a filter layer, to prevent erosion of the underlying material. Permeable as well as impermeable revetments are applied. It is necessary that the material used is flexible and tight to follow the compaction of the underlying sediment.

Dissipative Beaches

Douglas J. Sherman
Department of Geography, University of Alabama,
Tuscaloosa, AL, USA

Definition and Classification

Dissipative beaches are systems where most wave energy is expended through the process of breaking. Guza (1974) was apparently the first to use the term dissipative beach. He indicated that the wave-energy status of a nearshore system could be determined using the surf-scaling parameter, ε :

$$\varepsilon = \frac{\alpha \omega^2}{g \tan^2 \beta}$$

where α is the wave amplitude at breaking, ω is the wave radian frequency ($\omega = 2\pi/T$, where T is wave period), g is the gravity constant, and β is the beach slope in degrees. The proportion of incident wave energy that is dissipated by breaking increases as ε increases. When ε is less than about

2.5, most wave energy is reflected off the foreshore. For beaches where ε is larger than 20, most energy is dissipated by the turbulence associated with wave breaking. Guza (1974) designated these latter beaches as dissipative. Thus, the relative degree of dissipation or reflection of incident wave energy in a nearshore system has been used as a rationale for the classification of beaches. This is usually accomplished under the rubric of nearshore morphodynamics.

Morphodynamics

The concept of nearshore morphodynamics was developed to characterize systems where form and process are closely coupled through feedback mechanisms (Wright and Thom 1977; Short and Jackson 2013). On beaches, waves ($q.v.$) interact strongly with sediments and morphology, and the form of wave breaking is one manifestation of these interactions. For constant wave steepness, H/L (where H is wave height), the breaker type will change as the nearshore slope changes. On a very low-gradient slope, spilling breakers would be expected. As the gradient increases, there should be a progression through plunging and collapsing breakers. Finally, on very steep beaches, surging breakers should occur (Galvin 1968). For a constant nearshore slope, the same sequence of breaker types will occur as wave steepness decreases, i.e., steep waves are usually associated with dissipative beaches. Breaker type is closely associated with the expenditure of wave energy in the nearshore (e.g., dissipation or reflection) and the development of nearshore morphology. The morphology, in turn, controls breaker type. These relationships are the underlying bases for the concept of

Dissipative Beaches,

Fig. 1 The dissipative beach system at Rosstown, Co. Donegal, Ireland. Note the low-gradient beach slope and multiple lines (at least 10) of spilling breakers. Maximum breaker height is approximately 1.5 m, and period is about 7 s

nearshore morphodynamics (see summary by Wright and Short 1984). The recognition of characteristic sets of dynamic relationships provides the basis for using morphodynamic regimes (or states) as a means for classifying beach types. For example, spilling breakers tend to occur on dissipative beaches. This contrasts with reflective beaches (*q.v.*), where collapsing or surging breakers are common. Plunging waves tend to occur on the intermediate beach states of the morphodynamic model, where neither dissipation nor reflection dominates the response of nearshore morphology.

Characteristics of Dissipative Beaches

In cross section, morphodynamically dissipative beaches display the classic forms of “storm” or “winter” beach profiles (e.g., Sonu and Van Beek 1971). According to Wright and Short (1984), other distinguishing characteristics include low-gradient nearshore and beach slopes, about 0.01 and 0.03, respectively, and with relatively fine sediment sizes. Dissipative beaches tend to have a substantial sediment volume and at least one linear nearshore bar, although multiple bar-trough systems are common. In dissipative systems, the beach and nearshore zone will exhibit minimal alongshore variability – the system is approximately two-dimensional. Incident wave energy is maximum at the break point and decreases shoreward. The classic dissipative system displays several coincident sets of spilling breakers (Fig. 1), and there is minimal energy remaining at the landward extremity of uprush. Infragravity motion dominates the inner surf zone and frequently causes linear scarping of the foreshore (e.g., Short and Hesp 1982). On meso- and macrotidal beaches, the nearshore may be dissipative only at lower tidal stages and reflective at high tide (Short 1991; Masselink and Hegge 1995). Short and Hesp (1982) have also linked the dissipative beach state to the formation of large-scale transgressive dune sheets – at least in the Australian context. This linkage was a key development for the derivation of later models of beach-dune interaction (e.g., Sherman and Bauer 1993). Coastal ecologists have linked beach states with species richness and abundance (Defeo and McLachlan 2011), finding both to be enhanced in macrotidal dissipative systems.

Definition of Dredging

Dredging is moving material submerged in water from one place to another in water or out of water with dredging equipment. Dredging is applied in projects of navigation, for maintenance of beaches, for reclamation, to secure construction materials, and for environmental dredging.

Per Bruun: deceased.

Dredging for Navigation

From the very beginning of civilization, people, equipment, materials, and commodities have been transported by water. Ongoing technological developments and the need to improve cost-effectiveness have resulted in larger, more efficient ships. This, in turn, has resulted in the need to enlarge or deepen many of the rivers and canals, our “aquatic highways,” in order to provide adequate access to ports and harbors. Nearly all the major ports in the world have at some time required new dredging works—known as capital dredging—to enlarge and deepen access channels, provide turning basins and achieve appropriate water depths along waterside facilities. Many of these channels have later required maintenance dredging, that is, the removal of sediments which have accumulated in the bottom of the dredged channel, to ensure that they continue to provide adequate dimensions for the large vessels engaged in domestic and international commerce.

Dredging for Construction, Reclamation, and Mining

Dredging is an important way of providing sands and gravels for construction and reclamation projects. In the last two decades, the demand, and the associated extraction rates, for such offshore aggregates have significantly increased. Dredged aggregates have a wide range of uses.

Dredging for the Environment

Dredging can be undertaken to benefit the environment in several ways.

Dredged materials are frequently used to create or restore habitats. Recent decades have also seen the increasing use of dredged materials for beach replenishment.

Another environmental use of dredging has been in initiatives designed to remove contaminated sediments, thus improving water quality and restoring the health of aquatic ecosystems. This so-called “remediation” or “cleanup” dredging is used in waterways, lakes, ports, and harbors in highly industrialized or urbanized areas.

Types of Dredgers

Dredgers come in two different classes: mechanical and hydraulic.

Mechanical types include the *clamshell* or *grapple dredges* (Fig. 1). Larger dredges of that type are no longer favored. The endless *chain bucket* (bucket-ladder) dredge (Fig. 2) was

Dredging of Coastal Environments, Fig. 1 The clamshell or grapple dredge. (Adapted from Bruun 1990b)

Dredging of Coastal Environments, Fig. 2 The bucket-ladder dredge. (Adapted from Bruun 1990b)

Dredging of Coastal Environments, Fig. 3 The dipper dredge. (Adapted from Bruun 1990b)

used widely earlier in Europe but not in the United States, although they were employed on a few projects like the Panama Canal. For environmental reasons they may still be placed back on the market.

The *mechanical dipper dredge* with its heavy bucket (Fig. 3) moved by a very strong arm and boom is still used for dredging relatively loose (usually not solid) rock. The bucket may be provided with special cast iron teeth. Its volume may be several cubic meters.

Dredging of Coastal Environments, Fig. 4 The plain suction dredge. (Adapted from Bruun 1990b)

Dredging of Coastal Environments, Fig. 5 The cutterhead pipeline dredge. (Adapted from Bruun 1990b)

Dredging of Coastal Environments, Fig. 6 The self-propelled hopper dredge. (Adapted from Bruun 1990b)

The *hydraulic dredge* is the most important piece of dredging equipment. The *plain suction dredge* (Fig. 4) has no cutter but sucks material off the bottom and discharges it through a stern connected pipe leading to a spoil disposal area.

The *cutterhead pipeline dredge* (Fig. 5) has a rotating cutter on the end of the ladder and excavates the material from *in situ* condition and discharges it through the stern to pontoon and shore pipe. The dredge is controlled on stern-mounted spuds and is swung from one side of the channel to the other by means of a swing gear.

The *self-propelled hopper dredge* (Fig. 6) has a large hopper in which the dredged material is loaded for later dumping through doors in the bottom. This type of dredge is normally employed where the water is too deep for a pipeline

dredge or where spoil areas for such a dredge are not available within economic distances.

The hydraulic dredge has, without any doubt, become the most important piece of equipment in the entire harbor engineering field. Without the dredge, commercial navigation of waterways and rivers would be ended. Waterborne industry would collapse. Ocean shipping as it is known would be nonexistent.

Hydraulic dredges dig canals, ports, and harbors, do maintenance dredging in rivers, canals, and waterways, and excavate for construction of piers, wharves, docks, dams, and underwater foundations. They provide spoil for the reclamation of swamps and marshes; they construct dikes and levees, and dredge sand, gravel, and shell, as well as coal, gold, diamonds, and many other minerals for commercial purposes. The dredge's scope of operation is broad. Most of them have cutterheads.

Small hydraulic dredges, 20–40 cm diameter pipe, operate in water only a few meters deep. Large dredges, 65–90 cm diameter pipe, require more draft but can dig to greater depths. With the aid of booster pumps the distances solids can be pumped are unlimited.

Although the dredge's output is understandably greater in soft materials than in hard, it can excavate almost anything. It digs mud, silt, loam, clay, sand, hardpan, gravel, coral, and even rock. Boulders weighing 500 kg and more have been excavated and transported by dredges.

The self-propelled hopper dredge moves freely without any kind of mooring system. It can operate by pumping holes in the bottom side by side through a usually circular intake which is the reinforced end of the suction pipe, or it can trail along with its trailing suction head attached to the end of the suction pipe "vacuum cleaning" the bottom. This method is more practical and effective than the plain pipe sucking procedure where deep holes may become sediment traps for material which otherwise may have been flushed away. Various organizations like the IADC (International Association of Dredging Companies), the CEDA (Central Dredging Association), the WEDA (Western Dredging Association), and the WODA (World Organization of Dredging Association) organize conferences and publish magazines (See "Abbreviations").

Special Dredgers

Wheel Dredgers

The IHC's (The Netherlands) Scorpio Dredger has a dredging wheel that consists of bottomless buckets to which sticky soil does not adhere (Fig. 7). They are arranged to form a tunnel from which dredged material cannot easily escape. This effectively prevents the ingress of debris. The result is higher solids concentration, no spillage or blockage, and reduced downtime. Several such dredgers are now in operation all over the world.

Dredging of Coastal Environments, Fig. 7 The Wheel dredger SCORPIO. (Adapted from Bruun 1990b)

Dredging of Coastal Environments, Fig. 8 The sidecaster and hopper dredge McFarland. (Adapted from Bruun 1990b)

The Water Injection Dredger

The Water Injection Dredge (WID) was developed in Europe in the mid-1980s and has been used regularly there since 1987 and recently tested in the United States by the US Army Corps of Engineers (USACE). The principle of WID is to fluidize the shoaled material to a condition that a gravity-driven density current is formed, which transports the sediment down a slope into deeper water where it is no longer an obstruction to navigation, and natural sediment transport processes can take over. This density current remains close to the bottom, minimizing turbidity. Fluidization is accomplished by injecting water directly into the sediment voids under relatively low pressure, through a series of nozzles evenly spaced on a horizontal pipe. A pump mounted on the dredge, barge, or other vessel forces water into the horizontal pipe or head. The pipe pivots from the dredge, allowing the head to be lowered with the aid of a winch. During operation, the head with the injection nozzles is as close to the bottom as possible, while the dredge proceeds across the cut area (Bruun 1990a, 1996).

Sidecasters

Sidecasters sidecast the dredged materials. They come in various sizes. Small sidecasters are excellent for emergency and shallow water operations, for example, in channels.

The McFarland (Fig. 8) also has a hopper. It was put in commission in 1967 and assigned to maintenance of Gulf Coast inlets (USACE). It is 91 m long, 22 m wide, with a loaded draft of about 7 m to permit efficient operation in relatively shallow water.

Other types of dredgers are mentioned in the following section on the latest development of dredging equipment.

The Latest Development in Dredging Equipment

The latest decades and years have produced dredging equipment on a scale never seen before including hopper dredgers of capacities up to 33,000 m³, with suction pipes of 1.4 m diameter reaching down to 60 m depth, with deep dredging

suction up to 131 m depth, and outputs exceeding to 10,000 m³/h. Large projects in the Far East (Hong Kong, Singapore, Thailand, China, Persian Gulf) and also in South America (Argentina, Uruguay) utilize these dredges. Large fills for industrial development including airports, deepening of navigation channels and basins all over the world are in progress or planned. This includes many projects in the United States (New York, Charleston, Savannah, Galveston, Los Angeles, Columbia River, etc.). Materials are used for fills or dumped offshore in designated areas.

The dredging companies involved are mainly Dutch or Belgian. They compete in producing the most effective equipment provided with the latest inventions in survey technique, controls, and maneuvering. They are applied in projects with quantities of tens of millions of cubic meters capital dredging. Smaller size equipment includes hopper dredgers of a few thousand cubic meters hopper capacities for relatively smaller projects, capital as well as maintenance.

Some larger cutterhead hydraulic pipeline dredgers are still being built, in particular for work on harder bottoms and in narrow or protected environments. Some of these are ocean-going with discharge pump capacities of many kilometers. An example is the Bos Kalis 89 cm "ORANJE."

Amphibious "crawl cats" and "crawl dogs" (Bruun 1996) and underwater pumps like the PUNAISE (Visser and Bruun 1997) have been built and tested in practice.

One of the most recent additions to the international fleet is the "LANGE WAPPER," a 13,700 m³ capacity trailing suction hopper dredger which entered service in May 1999. The 20,000 dwt new vessel boasts the extremely shallow draft of 9 m fully laden, setting it in competition with vessels in the 8,000–10,000 m³ range-yet with substantially higher production rates.

Built by IHC Holland, the Lange Wapper is 120 m long, with a beam of 26.8 m. The total installed power is 13,400 kW and dredging depth is in the range 30–50 m. For a draught of 8 m, the vessel can carry a deadweight of 15,500 t.

The Lange Wapper features state-of-the-art computer software to integrate all dredging, navigation, and surveying systems. It is thought to be the first software of its kind in the industry.

Specially designed by DEME, together with IHC Systems (the electronics subsidiary of the IHC group), the software provides a single program capable of handling all data relating to dredging, navigation, and surveying. Previously, software systems could only communicate with each other from standalone packages. Furthermore, up to 10 extra

systems were required onboard and extra personnel needed to operate them. The software onboard the Lange Wapper will be available via a number of networked computer terminals and will also be able to access additional data by satellite.

Enhanced controls and accuracies are the main advantages of this new system. Tight dredging parameters will be possible, which will enhance performance in environmentally sensitive conditions and offshore trenching or pipe covering operations.

All dredging projects, however, depend upon hydrographic surveys. As ports and channel systems throughout the world continue to involve expansions and extensions, the need for effective survey programs becomes essential. Throughout the past year there have been some major developments within this sector of the port construction industry.

Dredging for Nourishment of Beaches

Artificial nourishment of beaches is the most practical and economical measure of coastal protection. Suitable material must be available. Figure 9 shows split-hull dumping of dredged material. Figure 10 is a trailing suction hopper dredge pumping material on the beach and in the nearshore bottom, or through a buoy connected to shore by a (submerged) pipeline. In the United States, nourishment is often done by a hydraulic pipeline dredge connected directly from the borrow area to the beach by (submerged) pipeline.

Profile Nourishment

The normal nourishment profile includes a wide horizontal berm with a front slope of about 1 in 10. Because beach nourishment is generally paid for by a public authority, public opinion is important in acquiring sufficient funds. Therefore, it is wise to design beach nourishment in such a way that the public sees that the beach is somewhat wider after the nourishment, but that there is no major adaption in the beach shape during the first storms in autumn. If the purpose of the nourishment is to make a wide recreational beach, this is very important. If the purpose is to prevent flooding, the best place is as high as possible on the beach. If the purpose is to combat chronic erosion, the best place is in the breaker zone.

Profile nourishment (Bruun 1990a, b) attempts to follow the natural profile in the nearshore as much as this is practically possible. The advantage of profile nourishment is that it decreases the introductory losses of fill producing a more stable condition. OVER THE BOW PUMPING (Fig. 10) is most suitable for such operations undertaken in countries like

Dredging of Coastal

Environments, Fig. 9 Direct dumping in the nearshore zone with hopper dredger. (From Bruun 1990b)

Dredging of Coastal Environments, Fig. 10 Trailing hopper dredger pumping through nozzle placed in bow of the vessel. (From Bruun 1990b)

Holland, Denmark, Germany and at its start in the United States. The Shallow Water Hopper dredgers, in short supply in the United States, are well suited for such operations. They may pump over the bow, if bottom is steep enough, or through a short pipeline (Bruun and Willekes 1992).

Dredging and the Environment

Introduction

The development of navigation requires still deeper and wider channels and basins, as well as fills for industrial harbor and other developments. This, in turn, carries with it the needs for major disposal areas for dredged materials.

Maintenance of depths requires removal of deposited materials which are sometimes or often polluted.

Beaches and shores are eroding and need protective nourishment by clean material which will then have to be relocated. Dredging may also be a useful tool for remedying past environmental interference. However, by its very nature, the act of dredging and relocating dredged material has an environmental impact. It is, therefore, of the utmost importance that we should be able to determine whether any planned dredging will have a positive or negative impact on our environment. Evaluation of environmental impact should examine both short- and long-term effects, as well as the sustainability of the altered environment.

While spoiling of material from dredging of tidal inlets on sandy shores has involved little difficulty because the material was clean and ample offshore dumping areas were available, dredging of harbors, estuaries, bays, lagoons, and waterways without tidal flushing, has gradually caused many problems with respect to the location of spoil areas.

In either case, a severe disturbance of the area's biology has resulted. This has necessitated a great number of regulations on the extent of such operations.

When using dredging techniques, we must be aware of the environmental effects of the changes we are trying to achieve, as well as the effects of the dredging activity itself which may include: alterations to coastal or river morphology; addition or reduction of wildlife habitat; changes to water currents and wave climates, which might affect navigation, coastal defense, and other coastal matters; reduction or improvement of water quality, affecting benthic fauna, fish spawning, and the like; improvement of employment conditions owing to industrial development; and removal of polluted materials and their relocation to safe, contained areas.

The marine environment is a complex combination of natural features and phenomena, supporting a diverse but largely concealed population. Because of this complexity it is extremely difficult to predict the effects of human-induced changes and short-term operations.

Past environmental ignorance has resulted in many rivers, ports, and harbors in the industrialized nations containing soils that have been contaminated by undesirable levels of metals and chemical compounds. When dredging in these soils, contaminants may be released into the water column and thence into the food chain. Thus, the environmental effects of dredging and relocation of the dredged material may be more severe and will require more detailed analysis. In certain cases, it is the very existence of the polluted soils that has led to dredging: by removing the polluted soils and relocating them to a more secure situation, the environment is improved. Long-term improvement does, of course, depend ultimately on preventing pollution at its source. The treatment and storage of polluted soils is a highly complex subject and requires detailed study.

Many rules and regulations have been issued regarding the handling of polluted materials. International conventions, for example, the London 1972 meeting (Bruun 1990a), have resulted in published advice. The PIANC (Permanent International Association of Navigation Congresses) has issued a number of guidelines including:

- Report of the International Commission. Study of Environmental Effects of Dredging and Disposal of Dredged Materials. Supplement to Bulletin No. 27 (1977)
- Report of the International Commission. Classification of Soils and Rocks to be Dredged. Supplement to Bulletin No. 47 (1984)
- Report. Disposal of Dredged Material at Sea. Supplement to Bulletin No. 52 (1986)
- Beneficial Uses of Dredged Material (1992)
- Dredged Material Management Guide (1997)
- Handling and Treatment of Contaminated Dredged Material, Vol. 1 (1997) and Vol. 2 (1998)
- Management of the Aquatic Disposal of Dredged Material (1998)
- Confined Disposal Facilities for Contaminated Dredged Material

The ADC (Association of Dredging Companies) and the CEDA have printed several reports, here particularly noted and referred to is the 1999 report on "Environmental Aspects

of Dredging.” In the United States, the USACE, Coastal Engineering Research Center in Vicksburg, MS, through its Dredging Research Division has published a great number of reports as mentioned later.

Management

Management alternatives for dredged material can be grouped into the following four main categories (listed in order of significance): beneficial use, open-water disposal, confined disposal, and treatment.

Beneficial Use

The definition of “beneficial use” according to the Dutch ADC and CEDA Guide #5, 1999, is “any use which does not regard the material as a waste.”

Dredged material is increasingly regarded as a resource rather than as a waste. The London Convention’s Dredged Material Assessment Framework (DMAF) recognizes this by requiring possible beneficial use of the material to be considered before a license for sea disposal may be granted.

Open-Water Disposal

Open-water disposal is the placement of dredged material at designated open-water sites in oceans, estuaries, rivers, and lakes such that the dredged material is not isolated from the adjacent waters during placement. Open-water disposal generally involves placement of clean or mildly contaminated material.

Open-water disposal of highly contaminated material can also be considered with appropriate control measures. This category includes unrestricted placement on flat or gently sloping waterbeds in the form of mounds or placement with lateral containment (e.g., depressions). For contaminated material, a cap of clean material can provide isolation from the benthic environment. If capping is applied over the mound formed by unrestricted placement, it is called level-bottom capping (LBC). If the capping is applied with lateral containment, it is called contained aquatic disposal (CAD).

Confined Disposal

Confined disposal is the placement of dredged material in an engineered containment structure (e.g., dikes, natural, or constructed pits) enclosing the disposal area and isolating the dredged material from surrounding waters or soils during and after placement.

Treatment

Treatment is defined as a way of processing contaminated dredged material with the aim of reducing the amount of contaminated material or reducing the contamination to meet regulatory standards and guidelines. Each project may

raise environmental concerns and not only when the material in question is contaminated. For instance, the “beneficial” use of clean, beach-compatible sand for beach nourishment may damage well-established sensitive marine habitats or species. Or the unrestricted open-water placement of clean material may have unacceptable direct physical impacts, such as smothering of bottom-dwelling organisms or local increases in suspended solids concentrations.

Assessments

The environmental assessment of management alternatives (with controls) should consider all potential impacts. Many countries require Environmental Impact Assessment (EIA) studies to be undertaken and the results must be documented in formal Environmental Impact Statements. (EIS.) Even if the law does not require such studies, it is advisable to include them in the project planning as EIS may prove to be very useful in the permitting procedure and in gaining public acceptance for projects.

For decision making, the following eight steps are identified in the Dutch Guide #5, by the IADC and WEDA (1999): establishing the need for dredging, characterization of dredged material, assessment of beneficial use options, preliminary screening of potential disposal alternatives, detailed assessment of disposal alternatives, selection for final design and implementation, permit application and processing, monitoring program design.

The World Bank (1990) distinguishes five main types of dredged sediments:

1. Material from maintenance dredging of ports, harbors, and navigation channels usually consist of fine-grained silt and clays and is often rich in organic matter and contains contaminants.
2. Material from maintenance dredging of sand bars at the entrances to harbors or channels usually consist of fine- to coarse-grained sand and is much less contaminated than (1).
3. Material from capital dredging within a port may vary considerably along the vertical profile. The upper layer is usually fine-grained, organic-rich, and contaminated, and the underlying layer is coarsegrained and uncontaminated. In some circumstances, even the deeper layers might contain elevated levels of contaminants from historical discharges.
4. Material from capital dredging of channels or outer harbor areas is likely to be coarse-grained and uncontaminated.
5. Material derived from remediation dredging is usually fine-grained, organic-rich and, by definition, highly contaminated. Its relocation requires special control measures.

Physical Properties

The basic physical characteristics are form and composition, grain size, specific gravity, plasticity, water content, shear

strength, water-retention characteristics, permeability, settling behavior, consolidation behavior, compaction, and organic content.

Chemical Properties

They include pH-values, calcium carbonate equivalent, cation exchange capacity, salinity, redox potential (electrified activity), dissolved oxygen, biochemical oxygen, organic carbon, nutrients, carbon/nitrogen ratio, potassium, and contaminants of any kind.

Biological Properties

Biological characterization of sediments may involve testing for the presence of microbial constituents and testing for toxicology.

Microbial constituents of concern include pathogens, viruses, yeasts, and parasites. Sediments should be tested for these constituents whenever dredging sites are close to sewage discharges and placement sites are close to sensitive areas such as drinking water intakes, recreation beaches, or shellfish beds.

Acute toxicity bioassays test the effects of short-term exposure. Toxicity is expressed as median lethal concentration (LC_{50}), that is, concentration which theoretically would kill 50% of the test organisms within a specified time span. The duration varies from hours to days.

Chronic toxicity bioassays assess sublethal effects which can result from prolonged exposure to relatively low concentrations. Such effects include physiological, pathological, immunological, teratological, mutagenic, or carcinogenic effects. Chronic toxicity bioassays may take several weeks. Toxicity bioassays may be used to evaluate: potential impacts of dissolved and/or suspended sediments on water-column organisms (elutriate bioassays); and potential impacts of deposited sediments on benthic organisms (benthic bioassays).

Metals

Metals may exist in the aquatic environment in four basic, but interactive forms. These dissolved forms are: free metal ions; complexed molecules; particulate forms absorbed to the surface of solid particles; and precipitates (mostly sulfides).

In free mode (the most toxic), metals are transported with the water and easily taken up by organisms. The particulate associated forms are relatively inactive. In sediments under natural conditions (anoxic, reduced, near neutral pH) only a small fraction of heavy metals is dissolved; the major portion is bound by sulfides or by structurally complex, large organic compounds. Release of these may be induced by increased salinity, reduced pH, and increased redox potential.

Sediment Properties Versus Dredging Placement Methods

In addition to the original properties at the dredging site, the behavior of sediments during and after placement will also

largely depend on the specific characteristics of the dredging and placement techniques.

Dredging techniques may be subdivided into two categories: mechanical and hydraulic dredging.

Mechanical dredgers (e.g., bucket or clamshell) use mechanical force to dislodge, excavate, and lift the sediments. The material is generally placed and transported to the site of discharge by barges. Barges may have bottom doors or split-hulls and the material can be released within seconds as an instantaneous discharge. Cohesive sediment dredged and placed this way remains intact, close to the *in situ* density through the whole dredging and placement process.

Hydraulic dredgers remove and lift the sediments as a slurry (mixture of sediment solids and large amounts of dredging site water). The slurry is transported to the discharge site via pipeline or in hoppers and released with large amounts of entrained water. Hoppers may release the material through bottom doors or through pump-out operations. Hydraulic dredging and transport break down the original structure of sediments.

Beneficial Use of Dredged Materials

The main application is for fills. Recent years have also introduced a number of practical structural usages.

Publications providing guidance on beneficial use include: Beneficial Uses of Dredged Material; Engineer Manual (USACE, 1986); Beneficial Uses of Dredged Material, A Practical Guide (PIANC, 1992); Handling and Treatment of Contaminated Dredged Material (PIANC, 1997); Guidelines for the Beneficial Use of Dredged Material (HR Wallingford, 1996).

Engineering Usages

For practical use of dredged materials, one may distinguish between rock, gravel, sand, silt, mud, and clay, differing greatly in grain sizes and shape. Sand and silts may become "quick." Clay is cohesive.

Gravel and sand are dredged for construction purposes. Different kinds of heavy minerals are extracted from sands in sometimes major operations, including from the deep sea (Bruun 1990a, b).

Coastal Protection

Dredged material is used for artificial nourishments of beaches which today is the most common coastal protection measure. The material dredged offshore or in entrances and navigation channels is pumped ashore if suitable for widening and raising the beach elevation.

Materials may also be used to produce protective offshore berms which may be designed as feeder berms, hard berms, and soft berms.

Feeder Berms

Feeder berms produced by dumping of materials nearshore serve partly as source of materials for a possible transfer of materials to the beach.

Hard Berms

The construction of hard berms involves the placement of suitable material, in depths up to 13 m, to create a permanent feature on the seabed approximately parallel to the shoreline with gentle side slopes that will intercept the troughs of incoming storm waves and decrease erosion of the shoreline. If the berm is made of sand, it will be modified in profile and some of the material will be lost, implying that some maintenance will be necessary. This technique may still be cheaper and more convenient (i.e., causing less disturbance to recreation) than direct beach nourishment.

Soft Berms

Naturally occurring underwater mudbanks are known to absorb water wave energy and thereby attenuate waves that pass over them. Energy reductions of 30–90% are not uncommon even in the absence of wave breaking. Attempts have been made to replicate this action by creating underwater mud berms from dredged material.

Open-Water Disposal

Material dredged may be disposed of in deeper waters or in shallow designated waters. Bypassing at tidal entrances is a common usage. Offshore disposals may be capped to protect the material from being eroded away. Polluted materials may be placed inside dikes. Figure 11 shows the large “Slufter” used by EUROPORT for disposal of dredged materials which are polluted. Land disposals may also use dikes. An

impermeable membrane is then placed to avoid penetration of pollutants to the surrounding areas. Material may also be placed in dredged pits in the bottom provided with a proper protective cover.

The Dredging Research Program in the United States by the USACE

The USACE is involved in virtually every navigation dredging operation performed in the United States. The Corps' navigation mission entails maintenance and improvement of about 40,000 km of navigable channels serving about 400 ports, including 130 of the nation's 150 largest cities. Dredging is a significant method for achieving the Corps' navigation mission. The Corps dredges an average annual 230 million m³ of sedimentary material at an annual cost of about US \$400 million. The Corps also supports the US Navy's dredging program in both maintenance and new work.

The Corps will continually be challenged in pursuing optimal means of performing its dredging activities. Implementation of an applied research and development (R&D) program to meet demands of changing conditions and generation of significant technology, adopted by all dredging interests, are means of reducing the cost of dredging the nation's waterways and harbors.

The Shallow Water Hopper dredger has always been on their agenda. There are a couple of additions to the fleet financed by private industry. They are of medium-size with about 5,000 m³ hopper capacity.

Reports on the development of dredging and on the Environmental Effects of Dredging, Technical Notes, are published regularly, the latter category covering the subjects

Dredging of Coastal

Environments, Fig. 11 The “Slufter” offshore diked disposal are used by EUROPORT (Rotterdam) for polluted materials. (Adapted from Bruun 1990b)

of Aquatic Disposal, Upland Disposal, Wetland Estuary Disposal, Regulatory Management, Beneficial Uses, Equipment, and Miscellaneous as described in numerous reports. Copies may be acquired from the USACE, Waterways Experiment Station, Vicksburg, MS.

The Long-Term Effects of Dredging Operations (LEDO) program by the Dredging Research Division of the USACE, Vicksburg, MS, “focus on cost-effective, environmentally responsible techniques for dredging and dredged material disposal in aquatic, wetland, and upland environments. Current research emphasizes risk-based procedures for effects assessment, exposure assessment, and risk characterization. The Program objective is to provide the latest proven technologies for identifying, quantifying, and managing contaminated sediments in support of cost-effective, environmentally responsible navigation.”

The primary benefit is a more timely complete, and cost-effective execution of the Corps’ responsibilities under the Clean Water Act (CWA), Marine Protection, Research, and Sanctuaries Act (MPRSA), Resource Conservation and Recovery Act (RCRA), and Water Resources Development Act (WRDA). This R&D program provides dramatic cost avoidances annually for achieving restoration goals for contaminated dredged material disposal as mandated by law.

Recent major products include:

1. A chronic/sublethal and genotoxic assay that meets national regulatory requirements.
2. National guidance for confined disposal facility contaminant loss assessment procedures. The guidance document was established as Corps policy to meet regulatory mandates.
3. A new analytical screening method that measures bioavailable dioxin and similar compounds with a 90% reduction cost and time required by previous methods (co-sponsored with another research program).
4. The Environmental Residue Effects Database (ERED), the first WWW-accessible database of bioaccumulation effects to improve the accuracy and defensibility of environmental impact predictions while significantly reducing evaluation costs.

LEDO research benefits/value-added to district projects can be demonstrated on a recent example. Since the bioaccumulation interpretation database is Web-accessible, it is immediately and cost-effectively available to all district projects in need of contaminated material assessment.

Dredging and disposal problems in the New York and New Jersey Harbors are mentioned in reports by WEDA (Mohan et al. 1999; Wakeman 1999). The World Bank 1990, has also issued its guidelines.

Conclusion

1. A strong development of the Dredging Industry is taking place with still larger and more efficient equipment. This development is most predominant in the low countries in Europe which virtually have taken over the world market.
2. Major projects on improvements of navigation channels and harbors remain. Artificial nourishment of beaches is still increasing.
3. Disposal areas for dredged materials are often running short due to environmental concerns. Diked areas, onshore and offshore, are becoming practices.
4. Environmental dredging is an important factor which requires much attention, planning, and monitoring. Beneficial usages of dredged polluted materials are developing.

Drift and Swash Alignments

Eric Bird

University of Melbourne, Melbourne, VIC, Australia

Definition

Drift alignments are found on beach-fringed coasts where the dominant waves arrive obliquely to the shore and (with accompanying currents) maintain a beach parallel to the direction of the resulting longshore drift. They are typically found on straight or saliented coasts where the obliquely-arriving waves move sediment alongshore. Swash alignments develop where beaches have been shaped by waves arriving parallel to the shore, usually in curved patterns resulting from wave refraction. They are typically found in embayments where longshore drifting is limited and beach outlines run parallel to the crests of incoming waves.

Drift and Swash Alignments

Drift and wash beach alignments are seen where an incoming south-westerly swell has produced beaches with drift alignments in Western Port Bay, Australia, and beaches with swash alignments on adjacent Phillip Island (Fig. 1). Drift and swash alignments can be developed experimentally on beaches in a wave tank (Davies 1980, Fig. 90): they are sometimes described as drift-dominated and swash-dominated beaches.

Drift Alignments

Drift alignments are best developed where waves arrive at an angle of 40–50° to the coastline. They are typically sinuous in detail, with intermittent lobes and cusps that migrate down-drift (with erosion on one side compensated by accretion on the other), and longshore spits and bars that diverge slightly alongshore. Tidal inlets also migrate alongshore, are deflected down-drift, and may be sealed off occasionally by drifting beach sediment. Variations in transverse profile occur as these features pass along the beach. A cyclic equilibrium may be attained where the beach alignment becomes adjusted in such a way that oblique waves impinging on the shore provide sufficient energy to transport the sediment arriving at one end of a drift-dominated beach through to the other, the configuration being maintained. Most beaches on drift alignments have an entirely updrift source of sediment (eroding cliffs or a fluvial input), but some incorporate sediment

Drift and Swash Alignments,

Fig. 1 South-westerly swell entering Western Port Bay, Victoria, Australia, produces drift alignments on beaches to Sandy Point and along the north coast of Phillip Island, and swash alignments in bays on the south coast of Phillip Island, notably at Woolamai Beach (Copyright-Geostudies)

derived from eroding cliffs or river mouths along the shore, as on the north coast of Hawke Bay, New Zealand (Bird 1996).

If the angle of wave incidence becomes greater or less than the optimum $40\text{--}50^\circ$ there is a slackening of longshore drifting and consequent deposition of sediment, but the drift alignment is soon restored when the oblique waves return to the optimum angle. A beach alignment can also be changed by variations in the rate of updrift sediment supply, and by erosion or accretion on updrift sectors of the coast.

Interruptions of longshore drifting result in changes along a drift-dominated beach. Projecting breakwaters designed to protect and maintain a harbor entrance show accretion on the updrift side and erosion downdrift: a well-known example is seen at South Lake Worth in Florida. The problem is often countered by introducing by-passing, whereby beach sediment is pumped through pipes from the accreting shore to the eroding shore downdrift, artificially maintaining the longshore drift.

Some drift-aligned beaches terminate in spits, such as the Langue de Barbarie on the Atlantic coast of Senegal in West Africa, a longshore spit that has grown southward in response to the dominant north-westerly swell to end in recurves at the mouth of the Senegal River. Cuspate forelands and recurved (angled) spits may include both drift-aligned and swash-aligned beaches, and as sediment eroded from the drift-aligned shore is carried round the point to be deposited on the swash-aligned shore they migrate downdrift. Dungeness, on the south-east coast of England, is a major shingle foreland that has migrated in this way. Such structures were termed traveling forelands by Escoffier (1954).

Alternatively, beaches on drift alignments may end in sectors of accretion alongside headlands, river mouths, lagoon outlets, or protruding breakwaters.

Swash Alignments

Beaches on swash alignments are smoother in outline than those on drift alignments, but are subject to alternations of profile erosion and losses of sediment offshore during storms and profile restoration by onshore sediment flow during calmer phases, a sequence known as “cut-and-fill.”

Swash alignments are well developed on beaches in embayments where intervening headlands exclude waves from all but one direction. The curving beach behind Disaster Bay, in southern New South Wales, a narrow embayment between high parallel sandstone cliffs, has a swash alignment with an outline shaped by incoming refracted ocean swell, but too limited in length for oblique waves to generate much longshore drifting. Numerous parallel dune ridges indicate that progradation has maintained this curved plan.

Swash alignments are also well developed on beaches on open coasts where the incoming waves arrive consistently

from one direction. In these situations, there is typically a simple relationship between beaches with curving swash alignments and the pattern of incoming refracted waves. In southern Australia there are long, gently curving beaches which receive south-westerly ocean swell from the Southern Ocean, refracted by nearshore shallowing: Encounter Bay is a good example. South-easterly swell entering Jervis Bay on the east coast of Australia is refracted into wave patterns that fit the curving swash-dominated outlines of bordering bay beaches that face in various directions, and a similar pattern has been documented in Storm Bay, Tasmania (Davies 1980). On the New South Wales coast a series of long asymmetrical (“zeta-curved” from their resemblance to the Greek letter ζ) beaches has developed on swash alignments, where incoming southeasterly waves are refracted round intervening headlands. Swash alignments occur on beaches on the Atlantic coasts of Europe, as on the coast of South Uist in the Hebrides, Rhossili Bay in Wales, and the Bay of Audierne in France.

Once established, gently curving beaches on swash alignments maintain their outlines through cycles of cut-and-fill when beach material is withdrawn seaward from them by storm waves, then swept back onshore in by a gentler swell. Any temporary divergence between incoming wave crests and the coastline initiates local longshore drifting which quickly restores the swash alignment.

Maintenance of harbor entrances on swash-dominated beaches by constructing breakwaters results in accretion on both sides, as sand is swept in from the sea floor, and a looped sand bar forms off the entrance, which may impede navigation. This has occurred at Lakes Entrance, Victoria, Australia, where a harbor was established in 1889 by cutting an entrance through a sand barrier. Navigation is here maintained by continual dredging of the sand bar (Bird and Lennon 1989).

Intermediate Cases

Few beaches are entirely swash- or drift-dominated. Chesil Beach in Dorset is a shingle beach which has a swash alignment shaped largely by south-westerly swell and storm waves, but longshore drifting occurs when westerly waves move sediment south-eastward and when south-easterly waves move it back westward. This alternation has led to lateral grading of this beach from granules at the western end to pebbles and cobbles toward the south-eastern end, near Portland Bill (Bird 1996).

On the other hand, beaches on drift alignments such as Sandy Hook in New Jersey or the beaches north of the Columbia River in Washington State are occasionally modified by waves coming in parallel to the shore, and sometimes show alternations of cut-and-fill with onshore-offshore (swash-backwash) sediment movement. The existence of

parallel beach and dune ridges formed by progradation behind beaches that appear to be drift-dominated, as on the North Beach Peninsula in Washington and Orford Ness in East Anglia, indicates occasional significant swash domination.

Changes in Beach Alignments

A lateral transition from a drift alignment to a swash alignment occurs on drift-dominated beaches that curve into sectors of accretion alongside headlands or breakwaters.

Where a beach outline is more sharply curved than the approaching waves it is drift-dominated, with a convergence of longshore drifting of beach sediment toward the center of the bay, where the beach progrades until it fits the outline of the arriving swell and so becomes swash-aligned. Convergent longshore drifting in Byobugaura Bay, near Tokyo, has prograded the central sector at Katakai in this way, with the arrival of sediment derived from the erosion of the northern and southern parts, and a similar evolution from drift alignments to a swash alignment has taken place at Giulianova on the east coast of Italy.

Where the beach outline is less sharply curved than the approaching waves, there is divergent longshore drifting from the center until the beach outline fits the wave pattern, assuming a swash alignment. This has occurred on the shores of the Andalusian Bight, in southern Spain, where erosion of the central sector has been balanced by progradation at Matalascanas to the south and Mazagon to the north.

The beach on the northern flank of Rheban Spit, in southeastern Tasmania, was built and prograded on a drift alignment as long as it received a longshore sediment supply from the north, but when this diminished the coastline was reshaped by updrift erosion and downdrift accretion until it developed a swash alignment adjusted to waves approaching from the north-east.

On some coasts, paired or opposed spits bordering embayments have grown on drift alignments, as at the southern entrance to Menai Strait and in Portmadoc Bay in North Wales. Convergent growth of such spits can lead to the development of a curving beach that becomes swash aligned. Beach ridge patterns on the Swina barrier in Poland indicate such an evolution on the coast of the Pomeranian Gulf.

A change from a swash alignment to a drift alignment may occur where incoming wave patterns are modified by an artificial structure such as a breakwater, or by shoal deposition or the growth of a coral reef. At Kunduchi in Tanzania, the sandy coastline had prograded on a swash alignment under the dominance of easterly swell, but the growth of reefs and shoals reduced the effectiveness of these ocean waves, and allowed locally generated and previously subdominant southeasterly waves to supervene, resulting in erosion until the beach assumed a drift alignment.

Summary

Beach-fringed coasts develop alignments related to the pattern of incident waves. Where wave crests arrive at an angle to the coastline they generate longshore drift, and the beach has a drift-dominated alignment, where wave crests arrive parallel to a coastline they anticipate and shape beach outlines, and the beach develops a swash-dominated alignment on which longshore drifting comes to an end.

Driftwood

Thomas A. Terich
Center for Geography, MS9085 Huxley College
Western Washington University, Bellingham, WA, USA

One of the pleasures of beachcombing is viewing and collecting driftwood of innumerable shapes and sizes which have washed up on a beach. Driftwood is the collective term for all types of freely floating wood on a water body or lodged upon a beach. Driftwood can be found on most marine shores of the world, but is generally in highest concentrations along the shores of the middle and higher latitudes in the boreal forest and arctic regions of the world.

Trees along forested coastlines undermined by wave erosion are a source of driftwood and drift logs, but streams and rivers emptying into the sea are the primary contributors.

Limbs, root masses, and whole trees are eroded from the stream banks, or are products of logging practices or log storage and rafting. Trees and logs enter river channels to be transported down river during high flows or are lost within estuaries during log storage and log rafting. The drifting wood can become temporarily lodged in estuaries or flushed directly into the sea. One estimate is that over 30 million board meters of logs enters the sea annually from coastal logging operations from Alaska to California (Sedell and Duval 1985).

Driftwood Movements

The fate of driftwood discharged into the sea is determined by coastal winds, waves, and currents. Some driftwood can transit entire oceans ultimately washing up on some foreign shore. The majority of the wood afloat is more likely to be carried by nearshore waves and currents. Along the Pacific Northwest of the United States, nearshore waves and currents seasonally reverse. In the winter, southwesterly winds drive waves and nearshore currents to the north. Driftwood floating in these currents tend to end up on beaches far to the north from their river or estuary of origin. During the summer, northwesterly waves and currents carry driftwood southward along the Pacific coast. The volume of driftwood movement during the summer months is usually less as river flows are lower carrying fewer logs to the sea and waves are less energetic, dislodging less wood from beaches.

Large concentrations of driftwood are found along arctic beaches of Siberia, Canada, and Greenland. Rivers of northern Siberia and Canada's Mackenzie River carry driftwood into the Arctic Ocean during the summer. The wood is conveyed by the clockwise Pacific Gyral between the pole and Arctic Canada and the Transpolar Drift Stream from the New Siberian Islands toward the Svalbard and east coast of Greenland (Haggbloom 1982).

Driftwood on Beaches

Driftwood and floating logs are driven ashore by waves and rising tides. Smaller pieces of wood can be thrown high on a beach by waves. Large logs, 20–30 m long and 1–2 m in diameter are shoved up the beach face by the repetitive thrusting of oncoming waves. Strong storm-driven waves cram logs and driftwood into dense piles high on the beach face and backshore. Driftwood deposits differ in quantity along any given stretch of shore from a few scattered logs and smaller pieces of wood to huge matted piles up to 3 m high and tens of meters wide. The largest concentrations of driftwood are trapped in coastal embayments such as river mouths and pocket beaches. But large deposits can also be found on the backshore and berms of wide sand beaches and steep rocky high-energy beaches. The wood is driven high up

on the shore during storm conditions. There the wood may ultimately become buried by beach sediment. But for much of the wood, the beach is a brief stop off until it is again dislodged and refloated by the next series of storm-driven waves. The unrelenting pounding by waves and rolling in the surf chips away at the bark, branches, and root masses sculpting driftwood into smooth and artistic shapes.

Ecology of Driftwood

Driftwood is capable of remaining afloat for long periods of time. Large and small pieces attract growths of epifauna and flora as well as selected insects. It is well-known that both commercial and recreational fish are attracted to floating wood at sea. Tunas and dolphin-fish are routinely found under or near masses of driftwood (Gooding and Magnuson 1967). The reason is not clear, but it is thought that these fish are simply seeking shade or smaller fish attracted to the driftwood upon which they can prey (Maser et al. 1988).

Once lodged on beaches, accumulations of driftwood tend to trap wind-blown beach sand and coarser swash carried sediments. They create an organic fabric that helps beaches grow or accrete. This is probably best seen near river mouths where river-borne sediments and wood accumulate along the seashore forming sand spits mantled with driftwood and logs. If there is a sufficient volume of sediment delivered to the shore, driftwood helps to capture wind-blown sediment. The wood not only traps sediment but provides decaying organic matter for pioneering plant and dune grass species to take root. The buried wood also creates an internal structural fabric within the building beach or sand spit. It is not uncommon to see large drift logs buried many years ago protruding from the face of an eroding beach scarp. Carbon-14 dating of uncovered driftwood is useful in determining the ages of beach deposits and other environmental conditions. Thus accumulations of driftwood along beaches are thought to help stabilize and contribute to beach accretion processes. Conversely, accumulations of driftwood at the base of beach cliffs can become powerful forces of erosion by battering and abrading cliffs especially when driven by storm waves.

Numerous species of birds are attracted to accumulations of driftwood on beaches and within estuaries. Bald eagles, herons, and pelicans use the logs as perches to rest upon and capture nearby aquatic animals in the surf or mudflats of estuaries.

Driftwood Hazards

Driftwood clearly has some ecological benefits, but it also presents some liabilities especially for boaters and beachfront home owners. Floating driftwood, especially large logs, create a navigation hazard for ships and smaller pleasure boats.

Driftwood is found in highest concentrations near the shore, in bays, and estuaries generally in same location as ships and boats. Ships' hulls are usually strong-enough to withstand the impact of a floating logs, but damage can occur to rudders and propellers. Smaller pleasure boats traveling at high rates of speed are especially vulnerable to impact damage. Large pieces of driftwood can crack and even pierce hulls as well as inflict serious damage to rudders and propellers. In some waterways around the United States, driftwood is "tagged" with small flags for better visibility by boaters or hauled out of the water.

Shorefront property owners who build their homes closer to the shore than is wise are not only exposing themselves to wave erosion and flooding, but to the intrusion of their homes by wave-driven logs. Such incidents are relatively infrequent, but there are documented cases of large drift logs thrown into the living rooms of shorefront homes in Washington State's Puget Sound.

Beachcombers are attracted to the aesthetic beauty of beaches laden with driftwood. Unfortunately, the wood that is so attractive can also be hazardous. It is not uncommon to learn of a beachcomber who has been killed or injured by a drifting log thrown into the unknowing beach stroller. The State of Washington has posted signs along the shore warning the public of large driftwood.

Driftwood Management

Driftwood has long been harvested for firewood and even for minor building projects. For years the practice of harvesting driftwood from beaches has been accepted. However, some have questioned the advisability of continuing such practices, especially in light of the better understood ecological role driftwood plays in estuaries and on beaches. Recognizing the benefits of driftwood to natural ecological systems, the State of Oregon has adopted a policy prohibiting the removal of drift logs. This policy does not preclude the beachcomber from collecting pieces of driftwood, but it is intended to prohibit the large-scale removal of large logs for firewood or other uses. The State of Washington licenses individuals who wish to retrieve drift logs afloat or on beaches. Beyond licensing, Washington does not appear to have any driftwood removal policy applied to the general public.

Dune Ridges

Terry R. Healy
Earth Sciences Department, University of Waikato,
Hamilton, New Zealand

Dune ridges are known variously as “beach ridges” (Goldsmith 1985; Komar 1976), “parallel dunes” (Bird 1972) or “low foredunes” (Davies 1977). They are a product of a prograding coast with plentiful sediment supply, low tidal range, shallow nearshore slopes, and relatively low-energy refracted swell wave conditions (Fig. 1). Continuing progradation is associated with plentiful diathetic onshore sweep of beach sediment, alternating with episodes of cut and fill, leading to the formation of a series of beach ridges (Davies 1957). Each ridge is thought to represent the previous location of a beach berm, upon which over time a low foredune develops from “aeolian capping” (Bird 1972). The height and spacing of the dune ridges is also a function of the effectiveness of the dune colonizing vegetation in binding the sand.

Geomorphically dune ridges may be as low as 0.5 m in elevation above mean high water springs, but more typically 4–8 m high. In width they vary from 50 to 200 m, and individual crests may extend shore-parallel for many kilometers (Fig. 1). The ridge alignment parallel to the shore (hence their name “parallel dunes”) is suggestive of the swell wave environment breaker alignment. The ridges are normally composed of sand but may also contain gravel. The parallel dune fields are comprised typically of Holocene sands and may be some kilometers wide. For example, Komar (1998) shows an illustration of the dune ridge field at Nayarit, Mexico, which contain some 250 individual ridges which could have evolved in as short a time as 12–20 years, although Pethick (1984) suggests that time intervals between dune ridges more typically varies from 70 to 200 years.

Terry R. Healy: deceased.

Dune Ridges, Fig. 1 Parallel dune ridges and swales on the coast near the Nassau River mouth, Queensland. (Photo: J. Mabbutt)

Separating the dune ridges are low swales characterized by impeded drainage and sometimes containing swampy vegetation. The variation in drainage characteristics leads to a tendency for variation in soil development on the well-drained ridge where oxidizing conditions prevail compared with the impeded drainage swale where reducing conditions and the podsolization process lead to dune podsol soils.

Dune ridges are widely associated with Holocene sandy barrier systems. They occur particularly along the Atlantic and Gulf coasts, Mexico, and southeast Australia, and New Zealand. Stratigraphically the dune ridges consist of aeolian low-angle cross-bedding in fine sands overlying low-angle dipping laminae of the beach face and berm, which overly marine deposits of the shoreface. These dune ridge systems evidently formed relatively rapidly (within ~1,000–2,000 years) after the sea reached its approximate present level from the postglacial transgression, presumably as a result of an abundance of sand being swept up with the postglacial transgression.

Dynamic Equilibrium of Beaches

Robert G. Dean

Department of Coastal and Ocean Engineering, University of Florida, Gainesville, FL, USA

Dynamic equilibrium of beaches describes the tendency for beach geometry to fluctuate about an equilibrium which also changes with time, but much more slowly. Beaches, as discussed here, refers to the visible beach including the shore and its underwater extension to a depth that is nearly

Robert G. Dean: deceased.

static over the long-term. Beaches respond on a wide range of spatial and temporal scales to natural and anthropogenic forcing. Natural agents include waves, tides, currents, winds, and other elements whereas anthropogenic agents include interruption of sediment supply and induced subsidence through withdrawal of ground fluids including water and hydrocarbons. Changes of beach position can occur with or without corresponding changes in the beach profile volume. Over a long time period, coastline position can be considered as the superposition of a long-term trend about which substantial fluctuations occur. Some of these fluctuations are quasi-periodic and others appear random. The paragraphs below discuss the coastline trends followed by the fluctuations.

Long-Term Changes

Worldwide, the most dominant cause of long-term coastline change is sea-level rise. The global rate of sea-level rise is approximately 12 cm/century, although there is concern that global climate warming may increase this rate substantially in the future through melting of ice and thermal expansion of oceanic waters. The concept of an equilibrium beach profile is useful in considering the effect of sea-level rise on coastline position (Dean 1991). This has been formalized by Bruun (1962) as the so-called “Bruun Rule.” A sea-level rise will cause the profile to be out of equilibrium since the depth at a distance from the coastline is now greater than before and equilibrium can only be restored through a decrease in depth which, in the absence of external sediment addition, must be provided by volume eroded by coastline retreat. The Bruun Rule is a simple equation which depends on a number of factors including wave climate, and sediment characteristics and is expressed as the coastline retreat being a multiple of the sea-level rise, with the multiple usually ranging from 50 to 100. Thus in one century, the expected average worldwide coastline retreat would range from 6 to 12 m; however, the coastline trend at a particular location can deviate from this value by orders of magnitudes ranging from coastline retreat to coastline advancement. In addition, the Bruun Rule can be applied to *relative* sea-level rise resulting from natural or anthropogenically induced subsidence. An example is near the Mississippi River outlet where the relative sea-level rise rate is on the order of 10 times the worldwide rate noted earlier. Entire islands vanish in periods of decades.

Short-Term Changes

The most rapid short-term changes in coastline position occur during severe storms when the beach may retreat on the order of 50 m in several hours. The primary elements are the

elevated water levels (storm tides) and high waves which can cause significant modifications to the nearshore geometry including shore and dune retreat. As discussed for sea-level rise, the storm tide causes the profile to be in temporary disequilibrium and the waves provide the energy to accomplish the profile adjustment. Averaged over long sectors, the primary sediment transport during storms is seaward where a new deposit called an “offshore bar” may be formed or additional sand stored in an existing bar which may be displaced farther seaward during the storm. Elevated water levels and accompanying large wave heights can cause large coastline changes without corresponding changes in the sand volume in the profile. An example illustrating this is a wave tank in which the sand volume is constant; however, the sand can shift offshore resulting in coastline retreat. Coastline retreat associated with a storm and for which there is no volume change will generally be followed by coastline advancement and complete or near complete recovery of the pre-storm coastline position. The timescales of the recession and recovery (advancement) phases differ markedly with the recession occurring in hours to days and the recovery requiring months to years. The modes of profile recovery also differ. The profile changes during erosion as the sediment is transported seaward tend to occur with the profile “hinging” about a subaqueous point with the elevations decreasing landward of the hinge point and increasing seaward of the hinge point. The recovery phase is much more complex with the landward transport of sand occurring in individual sand “packets,” each of which, upon reaching the shore, advances the coastline seaward. During long periods of milder wave conditions following a major storm, a number of recovery packets may occur in order to complete the recovery phase. The interest in anticipating and designing for storm-induced beach and dune erosion has led to the development of numerical models (Kriebel and Dean 1985; Larson and Kraus 1989). These models are much more effective in representing the erosional phase than the more complex recovery phase. Seasonal coastline changes, described as the average annual coastline fluctuations are poorly understood and vary substantially for various coastlines. The seasonal coastline change range in Florida is approximately 10 m whereas along the south shore of Long Island, NY, the range is about 30 m. The range in southern California is relatively large and is evident by the presence of sandy beaches during summer and rocky beaches left as a lag deposit in the winter when the sand removed has been stored in the offshore bar. Studies have documented that these seasonal coastline changes are related to the wave characteristics with the seaward transport associated with higher waves of shorter period which generally occur in the winter and the landward transport occurring during the milder summer conditions. Some beaches experience somewhat organized beach fluctuations which vary substantially along the shoreline. These appear as “sand waves”

(Bruun 1954; Bakker 1968; Verhagen 1989; Thevenot and Kraus 1995) which propagate along the shore and may have amplitudes of tens of meters sometimes causing distress to property owners with homes located near the high-tide shoreline. The understanding of the causes and relative longevity of sand waves is poorly understood. Proximity to structures (natural or constructed) and/or inlets can increase the coastline fluctuations significantly relative to those along a long unobstructed coastline. The amplified fluctuations near structures is a result of changes in wave direction which causes accumulation of sand against and removal of sand from the beach adjacent to the structure. Similarly, high-tide shorelines in pocket beaches change their orientation in response to changes in wave direction causing large fluctuations near the ends of the beaches (Thompson 1987). The changes near inlets appears to be primarily due to the influence of and the interaction with the deposit of sand, termed the “ebb tidal shoal.” This feature can shelter the adjacent shores from waves causing accumulation, can shift in position thereby exposing the shore to increased wave energy and can release large amounts of sand to the shore in packets. Dredging of inlets can also cause large fluctuations (usually erosional) along the adjacent coastlines. Studies of the long-term coastline position data base in Florida has shown that the standard deviations around the coastline change trend line are approximately 10 m along long coastlines and are on the order of 50 m near natural inlets (Dean et al. 1998).

Summary

In summary, beaches are dynamic, generally exhibiting a trend of coastline change which can be either advancement or retreat, with fluctuations about this trend. Although the underlying processes governing beach change are well-understood qualitatively, our ability to predict quantitatively these changes is likely to remain poor for the coming decades.

Economics of Beaches

William B. Stronge

Florida Atlantic University, Boca Raton, FL, USA
Huizenga College of Business, Nova Southeastern University, Fort Lauderdale, FL, USA

Definition

Beaches are economic as well as natural resources. As natural resources, they add beauty to the coast and provide habitats for many creatures including birds and sea turtles. As economic resources, they provide services to people and properties that have an economic value. They also generate impacts on the economy and tax base.

Economic Services Provided by Beaches

An important service provided by the beach at the coast is reduced storm damage to upland properties (US Army Corps of Engineers 1996, Chap. 5). Beaches reduce storm damage by moving the waterline further from upland property. During storm events, water travels less far inland as a result of the beach, and so damage to upland property tends to be less. Of course, a beach does not eliminate storm damage to upland properties, and in severe storms it may provide little or no protection. For example, the coastline impacted by the center of a hurricane may receive little protection from its beaches, but the upland properties impacted by the outskirts of the hurricane may receive very considerable storm damage reduction from their adjacent beaches. The second major service provided by a beach at the coastline consists of the opportunity for recreation provided to beach users. Although there is no direct fee charged in most places for recreational access to the beach, such recreational services have economic value just like playing a round of golf or a visit to the movies.

Beaches also generate impacts away from the coastline. Chief among these are the impacts on the local economy of the expenditures made by tourists attracted to the beach as a recreational resource (*tourism and coastal development, q.v.*) (Schofield 1986, Chap. 14). There will also be benefits at the regional (e.g., state or province) level to the extent that tourists are attracted from outside the region and benefits at the national level from the spending by international visitors. The expenditures of beach tourists increase sales and production by impacted business resulting in increased business profits and increased earnings of employees. The well-known multiplier process, popularly called the “ripple effect,” will cause these economic benefits to be passed in a chain from frontline businesses to their suppliers and from employees of those businesses to businesses which provide goods and services to those employees. Of course, such positive economic impacts vary depending on the size of the economy, which is impacted. In small economies, many of these impacts are lost to imports. There may also be disbenefits from beaches. For example, the tourists attracted to the beaches may contribute to traffic congestion. The congestion in turn increases travel time in the local area, and the involuntary consumption of this time represents an economic loss to the travelers, which can be measured by their wage rates. Additionally, the congestion may increase the frequency of automobile accidents with associated property losses.

Government tax revenues will also be expanded as a result of beaches (Stronge 1998). The particular impacts, of course, will depend on the particular tax and fee structure in operation in the beach area. In many local communities in the United States, local communities obtain revenues by taxing property values. Beachfront property values tend to be higher than property values away from the beach partly because land use tends to be more intensive at the beach. That is, there are more hotels and high-rise apartment buildings at the beach. But, even beachfront single-family homes tend to have high values relative to homes elsewhere in the community. Other things being equal, land values on the beachfront

tend to be high relative to values elsewhere in the community because properties on the beach provide easier access to the recreational and amenity values of the beach. Structural values on properties tend to be positively correlated with land values, and so the high beachfront land values stimulate the construction of relatively expensive beachfront structures. It is not unusual to see small, inexpensive beachfront structures that are in good condition being demolished and replaced by larger, more expensive structures, because sharply increased demand for beachfront land has raised land values to levels where beachfront structures are out of equilibrium with underlying land values. The expenditures of tourists are usually subject to sales taxes, including accommodation taxes, general sales taxes, and taxes on gasoline. These revenue sources are favorably impacted by beach tourism. Finally, income taxes will tend to rise as a result of the increased earnings of workers in the tourist industry. Offsetting these positive impacts on governments may be the required increases in government expenditures resulting from beach tourism. Increased traffic congestion may result in increased expenditures for law enforcement personnel, for example. There will be increased expenditures to clean trash off the beaches and, perhaps, for lifeguards. The fiscal impact of a beach, therefore, is the net impact of the positive increases in government revenues less the required increases in the government expenditures.

Government Policies on the Beach

Governments regulate the activities of beachfront property owners because actions taken by one property owner may adversely affect nearby property owners or negatively impact the society at large (Fischer 1990). Many beaches are subject to *beach erosion* (*q.v.*), steadily diminishing in size on an annual basis. Beaches are often dynamic systems losing sand during some seasons and gaining sand during others. Along an unbroken stretch of beach, with no headlands jutting into the sea, sand tends to travel along the coastline, and it may travel in one direction during one season and reverse direction in another. The direction traveled tends to reflect the weather patterns and, in particular, the direction from which storms come. On an unbroken coastline with no headlands, storms move sand around on the beach, but net losses may be low. In some cases, storms may push sand upland away from the beach, and, in some cases, sand may be lost offshore. But in many cases, storms move sand away from the coastline, and then natural processes of wave action will return most of the sand to its original position after the storm is over.

Inlets, including gaps between coastal islands and river mouths, represent holes in the coastline, which interrupt the flow of sand along the beach. When the tide is coming in, sand

is pushed into the inlet, and when the tide is ebbing, sand is deposited offshore. These movements often lead to an offset in the coastline as beaches on one side of the inlet lose more sand than beaches on the other. The asymmetric losses reflect the fact that storms from one direction may be stronger than storms from another. When new inlets are constructed, or old inlets are improved, the equilibrium relationship between adjacent beaches is disturbed, and properties on one side of the inlet may be threatened by erosion. Such activities are usually undertaken to improve navigation, but they may also have desirable environmental consequences. In many cases, a regular program of dredging shoals that develop around the inlet can provide a source of sand for adjacent beaches that are adversely affected by the inlet. These involve intergovernmental cooperation, particularly about cost sharing, that were not resolved until comparatively recently in the United States. It may also be possible to bypass sand mechanically from an accreting side of the inlet to an eroding side. This relatively automatic beach maintenance program may be cost-effective, but sand bypassing often involves the construction of an industrial-type physical plant that may be viewed as unsightly by nearby property owners.

Beachfront properties away from inlets may also be threatened by erosion if they were originally constructed too close to the high waterline. Such structures tend to be relatively old, dating from a time when beaches were regarded as static and, perhaps, when storm events had widened a beach beyond its long-run equilibrium size. Older structures may also have been constructed at a time when regulatory authorities were unaware of the dynamic properties of the beach or when enforcement of regulations was inadequate. In any case, many beaches have properties that are in danger of damage from erosion. Under these circumstances, property owners will often construct structures such as seawalls or revetments to protect their properties from storm damage. These structures may interrupt the flow of sand to adjacent properties or accentuate the force of the waves experienced by neighbors. As a result, such structures tend to stimulate the construction of similar structures along entire segments of the coastline. The actions of the first property owners have negatively impacted their neighbors, and because the structures protrude into the beach area, the actions reduce the beach available to the public for recreational purposes and to birds and other creatures, which use the beach as a habitat. To avoid such negative externalities, governments regulate activities of beachfront property owners including requiring building setbacks and requiring erosion control structures, to pass through a permitting process. In the United States, all three levels of government require permits for beachfront construction. This occurs because beach systems cross local government boundaries and, in some cases, state boundaries and because there is a national interest in protecting wildlife and other environmental resources.

Beach Nourishment

In some cases, erosion control may be accomplished by placing sand on the beach to widen it, often called *beach nourishment* (*q.v.*) (National Research Council 1995). The conditions that would make beach nourishment successful will depend on the strength of the forces causing erosion. Additionally, it must be possible to obtain a source of sand that is cheap enough to make the project economically feasible. In other cases, it may be appropriate to relocate properties further away from the high waterline. This solution is most appropriate where there is available land to accommodate the relocated structure and where the structure is relatively small and easy to move. Such a structure might be a one- or two-story second home on a relatively large lot, for example.

When beach nourishment is an appropriate remedy for erosion (i.e., it would be successful), and when it is economically feasible, it has the added advantages of retaining the recreational and environmental values of the “natural” beach. Structural remedies, on the other hand, often reduce the available recreational beach and the available habitats for birds, turtles, and other creatures that use the beach. Additionally, off-beach benefits such as economic and fiscal impacts are also retained by beach nourishment as opposed to structural solutions. It is rarely economically feasible for one property owner, or even a small group of property owners, to undertake a beach nourishment project unless they own a relatively long stretch of coastline. This is because beach nourishment projects have large fixed costs largely unrelated to the volume of sand being placed on the beach. These include costs of sand searches, permitting costs, and mobilization and demobilization of equipment charges. For example, sand searches are expensive because not only must sand be found, but it must be compatible with the sand already on the beach. An archeological survey may be required to ensure that there are no archeological artifacts (shipwrecks) in the sand source. Various environmental studies may also be required as part of the permitting process. Additionally, equipment including a dredge may have to be brought from hundreds of miles away. Once at the site, there are setup charges and charges for dismantling the setup at the end of the project. On rare occasions, it may be possible to “piggyback” a small project on a large project that is occurring nearby, thereby greatly reducing the fixed costs incurred by the small project. But beach nourishment projects are highly complex, and it is difficult to group projects together because all projects may not be ready for construction at about the same time. Even when a relatively large group of property owners is interested in undertaking a beach nourishment project, they may not be able to agree on a formula for cost sharing. Beach nourishment is a public good in the sense that it is usually not possible to prevent consumers of the services provided by the beach from benefiting from the project unless they have paid

for them. This is because beach dynamics will redistribute new sand along the entire section of the beach, and property owners in the middle of the project will gain sand even if they have not paid. This is the well-known “free rider” problem associated with public goods. As a result, beach nourishment, when feasible, may not be selected by owners of properties threatened by erosion even when appropriate and, in principle, economically feasible. But because sand placement retains the recreational and environmental values of the beach, as well as the positive economic and fiscal impacts, society as a whole may wish to encourage beach nourishment when it is an appropriate remedy. Under such circumstances, governments may wish to encourage beach nourishment as a tool for erosion control (Stronge 1995). At a minimum, government may take a leadership role, financing initial studies and educating property owners about beach nourishment. In many cases, however, governments also subsidize construction and maintenance costs. Such subsidies, of course, will be part of a regulatory regime designed to discourage the use of structures to the extent legally possible.

Many beach projects combine nourishment and structural solutions. Projects adjacent to inlets include terminal groins designed to prevent end losses from nourishment projects. The groins also preserve the navigability of the inlet. Initial nourishment projects designed to restore a beach after a period of neglect may also contain breakwaters and other structural solutions to deal with subareas that are expected to experience relatively high rates of erosion during the life of the project. Additionally, as subsequent beach maintenance projects are undertaken, structural solutions may be included to provide protection to “hot spot” areas, that is, areas where local conditions lead to more rapid erosion than in the project as a whole.

Measurement Issues

Most US beach nourishment projects receive some federal subsidies through the Army Corps of Engineers budget. In order to qualify for such subsidies, beach projects must be economically justified, that is, they must yield benefits in excess of their costs. This requires an economic study to be undertaken in advance of project construction. The economic study projects the benefits and costs of the proposed project. A methodology has been developed over many years for projecting benefits.

A benefit projection methodology is, in effect, a model of how the project’s benefits are generated. Like all models, a beach projection methodology involves a simplification of reality. In particular, the model identifies a limited number of key benefits and does not attempt to include all the benefits of the project. Additionally, there are key parameters imposed exogenously on the model, such as the length of the planning

horizon and the discount rate used to convert future dollars to present worth or value. Given the potential for inaccuracy introduced by the modeling process, it is surprising that few follow-up studies have been undertaken that would evaluate the accuracy of the model in projecting benefits.

Because benefit projections are based on a model, there are a variety of issues that have generated some debate. First, most beach projects are justified on the basis of a very limited number of benefits, namely, property protection and recreational values. At the federal level, off-site benefits such as economic and fiscal impacts are not included, although these benefits may be of the most importance at the local level. The value of environmental benefits is not usually measured, although projects can be prohibited or forced into redesign if they have significant negative environmental impacts. Finally, there may be externalities from beach projects. A beach is a highly visible piece of infrastructure, and failure to maintain it may be used by potential migrants to a local community as an indication that the quality of invisible infrastructure (e.g., water, sewer) is poor. Restoration of the beach may lead to a general rise in property values over and beyond what would be predicted by projecting direct benefits.

Storm protection benefits are measured as the discounted value of expected dollar losses assuming the project is constructed, less the discounted expected dollar losses if the project is not constructed. The losses from storms are applied to structure values based on rules of thumb, such as assuming the proportionate dollar loss is twice the proportion of the structure that is damaged by a storm. Thus, for example, when 50% of a building is lost, all of its structure value is lost. Expected losses are calculated as the sum of the probabilities of storm events times the dollar losses resulting from those events. Storm protection benefits are discounted using an exogenously given real interest rate. The basis for the original interest rate is obscure, although it is adjusted regularly using a nominal interest rate on government securities. A lower interest rate makes it easier to justify projects, and a higher interest rate makes it more difficult. Opponents of Corps of Engineers' projects favor a high interest rate, while supporters of such projects favor a low rate. Some people favor basing the interest rate on the government bond yield, but others argue that this will favor public over private projects since government borrowing costs are lower than private borrowing costs. An alternative interest rate could be based on the home equity loan market, under the assumption that taxpayers had to borrow in order to pay their taxes. Beach benefits are discounted over a 50-year period, assuming that the project is maintained on a projected schedule. The 50-year planning horizon is somewhat arbitrary, although if the discount rate is high, future benefits and costs will be reduced to zero when discount factors are applied to values generated far into the future. Follow-up studies of the accuracy of projected maintenance intervals are needed.

Recreational benefits are measured based on willingness to pay by beach users. Two approaches have been taken. One is based on travel costs borne by the beach user, that is, out-of-pocket expenses and time expended by the beach user in traveling to the beach. This approach requires a variety of assumptions to be made about travelers. An alternative approach is to use surveys of beach users to collect information on willingness to pay. It is more common to conduct surveys as personal interviews on the beach rather than by telephone or mail in order to reduce nonresponse bias. There is a large literature in economics relating to contingent valuation surveys, including recommendations for wording questions (Portney 1994). One issue relates to whether the interviewee realizes that dollars expended on a beach visit are unavailable for alternative products. A second issue relates to allowing an interviewee to select from a list of willingness to pay values, as opposed to giving a yes or no to a single value. Interviewees may have a tendency to pick a middle value on a list. Collecting information by obtaining a response to a single value, the so-called referendum method, requires a larger sample size of interviewees. In the case of beach surveys, there are also unique problems. A certain number of people on the beach strongly oppose user charges for entry to the beach and report little or no willingness to pay values in an effort to discourage the imposition of such charges. There may also be a group who say that the value of the beach is infinite, since it is a beautiful natural resource. Finally, there are difficulties with estimating willingness to pay for beach improvements by interviewing users of the unimproved beach. The number of new users and the increase in average willingness to pay may have to be projected using very limited data.

Issues Relating to Funding Beach Improvements

Many beach projects take place on stretches of coastline where the upland properties are at least partly privately owned. Moreover, the average income level of beachfront property owners tends to be high since, as noted above, beachfront property values tend to be high. As a result, benefits from beach improvements may be skewed in the direction of relatively affluent beachfront property owners. In many cases, the public perception that benefits are skewed to beachfront property owners leads to the use of specialized funding sources as a means of financing government subsidies. Thus, for example, a special taxing district may be established to collect additional property taxes from beachfront property owners. In another case, a tax on accommodations may be used, particularly if such accommodations have large clienteles of beach users. In some cases, local funding is obtained by charging beachfront property owners for their storm protection benefits and by charging non-beachfront property owners for their recreation benefits.

In the United States, there are also issues about funding by level of government. Under current law, federally approved beach nourishments may receive subsidies in amounts up to 65% of the total cost for initial projects and up to 50% of the cost of maintenance projects. There are some peculiarities in the federal program for subsidizing beach nourishments. The federal government requires that projects seeking subsidies be economically justifiable based on storm protection benefits alone, and this is most easily achieved by projects with highly intense upland land uses, such as high-rise apartment buildings and hotels. On the other hand, the size of the federal government subsidy depends on the extent of public access and parking to the improved beach, that is, the size of the recreational benefits resulting from the beach improvement.

There have been efforts by the executive branch of the federal government to reduce the size of federal subsidies for beach nourishment projects. Most of these efforts have failed to obtain support in Congress. The Clinton administration attempted to limit the number of beaches that could qualify for federal subsidies by distinguishing between beaches of national interest and beaches of state and local interest in much the same way as highways are divided between national roads, state roads, and local roads. The same administration became concerned about the large subsidies that would be required to maintain existing projects, in an era of large budget deficits, and successfully reduced maintenance subsidies from a maximum of 65% of costs to 50%. Both the Clinton and Bush administrations believe that most of the benefits from beach projects accrue at the local level, and, therefore, they argue that most of the funding should be obtained from that level. They argue that, from a national viewpoint, economic and fiscal benefits represent a redistribution across regions rather than a substantial increase in the national totals. Recreational benefits also represent a redistribution, since beach users may use other beaches or alternative recreational facilities if a beach is not improved. The Bush administration has proposed lowering the maximum federal share to 35%. On the other hand, the federal government maintains control of local beaches as habitats for wildlife, and at least some erosion has been caused by navigation improvements to federally maintained inlets. The federal government is arbitrarily adjusting cost-sharing proportions without undertaking any study of the national benefits of beaches. Until such a study is undertaken, it is unlikely that an appropriate federal cost share will be obtained.

Beach Nourishment Outside the United States

In addition to the United States, beach nourishment projects have also been undertaken in other countries. Hanson et al. (2002) contain a comprehensive survey of beach nourishment project in Europe. The paper includes details on beach

nourishments in Denmark, France, Germany, Italy, the Netherlands, Spain, and the United Kingdom. In terms of the volume of sand placed by 1999, The Netherlands and Spain (with equal amounts placed) accounted for over 60% of the total placed by the seven countries. Germany was the only other country that accounted for more than 10% of the total. The Netherlands has a sandy coastline that is subject to erosion especially along its middle region, called the Holland Coast. A European Commission-financed EuroSION report dated 2007 can be found by searching for Holland Coast at <http://copranet.projects.eucc-d.de>. Most erosion is north of the mouth of the canal that links Amsterdam to the North Sea, and it has an important summer beach tourist industry. The plentiful supply of sand has ensured that beach nourishment has become the preferred method for combatting erosion since 1990. Most of Spain's beach nourishment projects are along its Mediterranean coast. Spain was the last of the seven countries to begin nourishing its beaches (1985), according to Hanson et al. The southeast coast has a relatively warm winter that has led to a substantial year-round beach tourist industry.

Beach nourishment in the European countries has a similar history to the US case. The use of this "soft" tool began in a small way in the 1950s and 1960s, but it was substantial by the 1980s. Many projects include a combination of nourishment and structures in Europe as in the United States. Hanson et al. note that the United States places more emphasis on storm damage prevention than do European countries. But it is inappropriate to compare a continental-sized country such as the United States (especially when Alaska with its long coastline is included) to a series of relatively small European countries. The emphasis on storm damage prevention in the United States reflects the historic role of the Federal Government in coastal protection and the primary role of the States in providing parks and recreation. Funding at the state level is driven by the desire to preserve the recreational value of the beaches and the associated tourist industries. US coastal communities are beginning to confront the impact of longer-term trends such as the rising sea level. They have much to learn from the Netherlands and other European countries in dealing with long-term threats to their coastal systems.

There is less beach nourishment activity in the rest of the world, although there are projects in Australia, and Hanson et al. include activity in South Africa in their Table 2 (Castelle et al. 2009). The Australian project in the Southern Gold Coast of Queensland includes a sand bypassing project.

Summary

Beaches provide services to people and properties that have an economic value. They also generate impacts on the economy and tax base. An important service is reduced storm damage to upland properties. They also provide an

opportunity for recreation to beach users. Beaches also generate impacts away from the coastline, especially the impacts on the local economy of the expenditures made by beach tourists. The well-known economic multiplier process will cause these expenditures and will cause these economic benefits to be passed in a chain from frontline businesses to their suppliers and from employees of those businesses to businesses which provide goods and services to those employees. Government revenues will also be increased, although there may also be increased government expenditures.

Governments regulate the activities of beachfront property owners because actions taken by one property owner may adversely affect nearby property owners or negatively impact the society at large. Many beaches have properties that are in danger of damage from erosion. Under these circumstances, property owners will often construct structures such as seawalls or revetments, and these may interrupt the flow of sand to adjacent properties or accentuate the force of the waves experienced by neighbors. As a result, such structures tend to stimulate the construction of similar structures along entire segments of the coastline. This may result in the loss of the sandy beach, reducing recreational opportunities and habitat for wildlife. Governments may provide leadership in developing soft solutions, especially beach nourishment. The large fixed costs of such projects make them economically infeasible for small groups of property owners, and their nature as public goods prevents free riders from taking advantage of the benefits while refusing to contribute to the costs.

A methodology has been developed in the United States for determining when beach projects are economically justified because the value of their benefits exceeds their costs. There are many debates about the individual parts of this methodology. These include which benefits should be included and how they should be measured. There also issues about how the costs should be apportioned among the different levels of government (federal, state, and local) and, in some cases, how costs should be shared among beachfront property owners themselves.

The history of beach nourishment outside the United States has been similar to the US experience. Toward the end of the last century, beach nourishment became the preferred policy option, although the projects also included structural solutions as well.

El Niño–Southern Oscillation (ENSO)

Henry F. Diaz

NOAA/OAR/CDC, Boulder, CO, USA

Local Fisheries (Enfield 1988, 1989)

The term El Niño (or “the child”) was originally used by Peruvian fishermen in the nineteenth century to refer to a Christmastime warming of coastal sea surface temperature (SST), often associated with an abrupt decrease in productivity of the local fisheries. The Southern Oscillation (SO) portion of El Niño–Southern Oscillation (ENSO) describes the global-scale surface pressure oscillation documented by workers around the turn of the century and first studied in detail by Sir Gilbert Walker (for historical reviews, see Rasmusson and Carpenter 1982; various chapters in Glantz et al. 1991; Diaz and Markgraf 1992, 2000; Diaz and Kiladis 1995; Allan et al. 1996; Diaz et al. 2001). It was not until the 1960s that Jacob Bjerknes linked the two processes and began to describe the complex interplay between the ocean and atmosphere, which comprises ENSO and can lead to dramatic perturbations of the global climate system. Here, we will be concerned with the implications of climatic change on ENSO, as well as considering the possible importance of ENSO itself for low-frequency climatic variability.

The root of what is now commonly referred to as ENSO lies in the tropical Pacific, although its influences eventually

spread far beyond that ocean basin. To begin to understand the ENSO cycle and its role in climate variability, the mean oceanic and atmospheric conditions over the eastern Indian and Pacific sectors are first considered, at least in general terms. We then examine the principal climatic anomalies worldwide that result from the development of the tropical anomalies. For further reading, see Streten and Zillman (1984) and Kiladis and Diaz (1989).

Mean Conditions

The South Pacific high-pressure system is the primary atmospheric circulation feature of the eastern South Pacific Ocean. This semipermanent surface high is associated with equatorward flow along the coast of South America, and strong southeasterly trade winds over the tropical eastern Pacific. These southeasterlies cross the equator and merge with the northeasterly trades of the north Pacific subtropical high at a latitude of about 80°N, giving rise to a zone of surface convergence and heavy rainfall known as the *inter-tropical convergence zone* (ITCZ). Further west, the southeasterly trades weaken and recurve into northeasterlies in the tropical southwest Pacific, merging with southeasterlies from surface high-pressure systems moving eastward from the region of Australia. This produces another northwest–southeast oriented rainfall maximum called the south Pacific convergence zone (SPCZ; Trenberth 1976).

The distribution of rainfall in the tropical Pacific is closely related to the SST pattern, which in turn can be understood to be driven by the surface wind stress and associated ocean currents (see Pickard and Emery 1982). One result of the Earth's rotation is to cause surface water to flow to the right of the wind in the Northern Hemisphere and to the left of the wind in the Southern Hemisphere. Thus, easterly trade winds along the equator result in a divergence of water away from the equator, which leads to the “upwelling” of relatively cooler water from depth to conserve mass. Similarly, equatorward wind stress along the western coast of South America leads to divergence of water away from the coast and strong upwelling along the steep subsurface continental margin. Regions of upwelling comprise productive fisheries areas, as the subsurface waters are often rich in nutrients. This effect, along with the northward transport of cold water in the Peru Current, gives rise to the rich fisheries and relatively cold SST for its latitude along the coast of Peru and the Galapagos Islands.

A direct result of the coastal and equatorial upwelling is to increase the stability of the atmospheric boundary layer by the cooling effect of the SST. This, along with the reduced evaporation over colder water, results in the strong suppression of rainfall in these regions. As a result, the coasts of southern Peru and northern Chile are the driest deserts on earth. Anomalously dry climates are also experienced along

the so-called “equatorial dry zone” in the central and eastern Pacific as a result of the strong upwelling there. As one moves westward, equatorial SST increases gradually as the trades and upwelling weaken, eventually giving way to the “warm pool” west of the dateline. This region is the largest area of high SST in the world's oceans, averaging greater than 28 °C. The warm pool extends west-ward from the western Pacific through the seas surrounding Indonesia and into the eastern Indian Ocean, and is associated with high precipitation over these regions.

The ENSO Cycle

ENSO fluctuations are associated with marked deviations from the mean atmospheric and oceanic conditions described above. In the eastern Pacific Ocean, its most obvious manifestation is an increase in SST along the equator and coast of South America, with an associated increase in sea level and depth of the thermocline. This results from a decrease in upwelling due locally to a weakening of the South Pacific high and associated trade wind flow, as well as the eastward propagation of equatorially trapped large-scale waves in the ocean, which suppress the thermocline (Philander 1990).

The weakening of the South Pacific high is the eastern component of Walker's Southern Oscillation and is associated with an increase in surface pressure over Australasia. Figure 1 illustrates how the surface pressure varies inversely between Tahiti (Papeete) and Darwin, Australia, on timescales of several months and greater. Various indices of the SO have been constructed utilizing normalized pressure anomalies between stations near the poles of the oscillation such as Darwin and Tahiti (see Trenberth 1984). However, the association between the SO itself and the eastern Pacific SST is not a simple one (Deser and Wallace 1987). The SO is most closely coupled to SST variability along the equator from about 160°W to the Galapagos, and only loosely related to SSTs near the dateline and in the traditional El Niño region of coastal Peru. Figure 2 gives the temporal evolution of normalized SST variations in the equatorial belt from 6°N to 6°S, 150°W to 90°W, which is known as the Niño-3 region (Rasmusson and Carpenter 1982). The correlation between the Tahiti minus Darwin sea-level pressure (SLP) difference and the Niño-3 SST is quite high (with about 64% of the variation in one series explained by variations in the other). The five most recent warm events can be seen on these plots, namely 1982–83, 1986–87, and 1991–92, 1997–98, a weak event in 2002–03, along with cold events in 1988–89 and 1998–2000.

Knowledge of the workings of the ENSO phenomenon can be obtained from an examination of its composite behavior (Rasmusson and Carpenter 1982), along with study of individual cases, which deviate markedly from this mean view (Fu et al. 1986). One interesting aspect of ENSO is the

El Niño–Southern Oscillation (ENSO), Fig. 1 Sea-level pressure anomalies at Tahiti and Darwin, Australia. Monthly departures have been smoothed with a five-month running mean, applied twice

El Niño–Southern Oscillation (ENSO), Fig. 2 Standardized SST anomalies in the El Niño-3 region for the period 1951 through July 2003. Reference period is the full period of record; monthly data have been smoothed with a three-month running mean, applied twice

tendency for phase locking to the annual cycle. ENSO extremes often first develop during the northern spring, when the trade winds are weakest and SST is highest on average over the eastern equatorial Pacific. The fundamental instability involved concerns a relationship between SST anomalies and atmospheric convection. In the majority of events, a positive equatorial SST anomaly develops initially near the dateline. Since SST in this region is on average about

28 °C, any positive anomaly in this region will create conditions conducive to anomalously active atmospheric convection (Barnett et al. 1991).

The development of ENSO events tends to peak during the late summer and early fall of the Northern Hemisphere. Notable exceptions occurred in the warm events of 1982, 1986, and 1991, which developed late in the calendar year and peaked during the northern winter and spring.

The feedback leading to a reversal of ENSO conditions is often mediated by the seasonal development of the strong trade wind regime of northern fall, as well as the depletion of heat energy in the warm pool. Much of this energy is apparently transferred to the atmosphere through anomalously high rates of evaporation, and portions of it may also be transferred to higher latitudes by the oceanic meridional circulation. Once the heat content of the ocean is depleted, the stage is set for the transition to the opposite phase of ENSO, the so-called “La Niña” or cold event (e.g., van Loon and Shea 1985; Philander 1985, 1990). Cold events also involve an unstable interaction, as described above, for warm events, except that it occurs in reverse, as cold SST in the eastern Pacific help maintain a strong westward pressure gradient and trade winds, in turn favoring the continuance of the SST pattern itself.

ENSO Teleconnections

Much of Gilbert Walker’s early work was geared towards prediction of Indian rainfall, and the SO was of great interest, as it was known that the strength of the monsoon was inversely proportional to the surface pressure over southern Asia. In his investigations, Walker (1923) established that high pressure over the Australasian region was accompanied by drought over India and Australia and cool, wet winters over the southeastern United States. Surprisingly, little work on atmospheric teleconnections was undertaken until nearly a half a century later, when Bjerknes (1966) uncovered evidence that El Niño conditions were associated with a strengthening of the storm track over the North Pacific. Since then, a wealth of work has been done on the temperature and precipitation signals associated with ENSO. Much of the synopsis that follows has been taken from the work on large-scale ENSO signals of Rasmusson and Carpenter (1982), Ropelewski and Halpert (1986, 1987), Lau and Sheu (1988), Kiladis and van Loon (1988), Kiladis and Diaz (1989), Diaz and Kiladis (1995), and Diaz et al. (2001).

Although the term “El Niño” was first used to describe the annual warming of the waters along the Peruvian coast, in the 1960s it became synonymous with the concurrence of abnormally high SST and heavy rains in the usually hyperarid Peruvian coastal plains. Bjerknes (1969) noted that anomalously heavy rains during El Niño also occurred at Pacific island stations such as Canton and Christmas in the equatorial dry zone. As mentioned above, this signal is one manifestation of the equatorward shift of the convergence zones during equatorial warming of the SST associated with ENSO. As a result, the regions normally under the influence of these convergence zones, such as the Caroline and Marshall Islands, Fiji, and New Caledonia, experience drier than normal conditions.

The most pronounced signals occur during the year that an ENSO extreme first develops (here called “Year 0”) into

the following year (Year +1), following the convention of Rasmusson and Carpenter (1982). ENSO appears closely tied to the Asian and Australian monsoon circulations, which are notably weaker during warm events (see Webster and Yang 1992). While precipitation increases in the central and equatorial Pacific during warm events, it becomes markedly drier over regions bordering the western Pacific and eastern Indian Ocean, such as Indonesia and Australia (Allan 1988; Nicholls 1992), India (Rasmusson and Carpenter 1983), and southeast Asia. Failure of monsoon rains during warm events can have catastrophic impacts (Kiladis and Sinha 1991). Conversely, cold events are often associated with flooding events in India (Parthasarathy and Pant 1985). The Australasian signal is more evident during the northern fall of year 0, and persists over the monsoon region of northern Australia into the December through February rainy season. However, during strong ENSO events, the entire continent of Australia can be affected by severe drought conditions (Nicholls 1992). See also the reviews in the special issue of the *Journal of Geophysical Research* [Anderson et al. (eds.) 1998].

It should be emphasized that, while warm events can result in devastating precipitation deficits over monsoon regions, these areas generally still receive a large amount of precipitation in all but the most extreme cases. Over certain regions of the data-sparse Indian Ocean, there is some suggestion that warm events actually see above-normal precipitation in phase with that over the central Pacific. Sri Lanka, the Seychelles Islands, and coastal stations of equatorial Africa are certainly wetter than normal during their September–November rainy season (Kiladis and Diaz 1989), and satellite data from three warm events (1982, 1986, and 1991) support the occurrence of enhanced rainfall over the southern Indian Ocean during the northern winter of those events. If so, this means that the main focus of precipitation over Australasia is actually not so much shifted eastward, but distributed more evenly across the equatorial Pacific and Indian Oceans.

As warm events evolve toward their “mature” phase during the northern winter season (DJF + 1), drier than normal conditions continue in the region of the western Pacific ITCZ from the Philippines eastward (Kiladis and Diaz 1989), and east of Australia in the normal position of the SPCZ (Kiladis and van Loon 1988). Similarly, a large region of southeastern Africa, including parts of Zimbabwe, Mozambique, and South Africa, has a marked tendency for drought during DJF + 1 of warm events. Precipitation in this region is highly seasonal, so this signal can have an especially large impact since it occurs during the normal southern summer rainy season (Nicholson and Entekhabi 1986). Farther north in Africa, there are indications that warm events favor drought conditions from the Sahel eastward to the highlands of Ethiopia during the normal summer rainy season of JJA 0 (see Janowiak 1988; Lamb and Pepler 1991).

While coastal Ecuador and northern Peru often experience flooding during warm events, other regions of the Americas often also register large rainfall anomalies. A consistent dry signal is found from JJA 0 through DJF + 1 over northern South America (Rogers 1988). Over northeast Brazil, the periodic occurrence of severe drought in the agriculturally rich Nordeste region in connection with El Niño events has resulted in severe economic hardship and occasional famines in this region (Hastenrath and Heller 1977; Chu 1991). Widespread and severe famine was reported during the great El Niño of 1877–78, while other severe El Niño episodes, including that of 1982–83, have led to great suffering. Although data are sparse, the northern Amazon basin also appears to be affected. In contrast, much of southern South America is wet during JJA 0, and this signal persists into SON 0 in Uruguay, and central Chile and Argentina (see Kiladis and Diaz 1989; Diaz and Kiladis 1995; Diaz et al. 2001). A remnant of this signal is still present in DJF + 1, when the southeastern United States and northern Mexico also shows above normal precipitation. In the heavy rainfall areas of the upper Paraná and Paraguay River Basins, MAM + 1 precipitation tends to be above normal, and this contrasts with the relatively dry summer wet season over Central America.

Although the best correlations between ENSO and temperature are observed in the tropics and subtropics, the Americas can experience large mid latitude temperature anomalies during ENSO events. Strong and relatively mild westerly flow from the Pacific into the North America during warm events is responsible for a large region of positive temperature departures from southern California northward along the west coast to Alaska, then inland across western and central Canada. This signal over northwest North America is one of the most reliable in the extratropics from event to event (Kiladis and Diaz 1989; Diaz and Kiladis 1992). Cold events are equally reliable in being associated with anomalously cold winter seasons in this region. In those years, a tendency toward a weak jet stream over the central Pacific leads to atmospheric “blocking” patterns in the Gulf of Alaska, which in turn are associated with anomalous northerly flow over northwestern North America. The increased warm-event storminess over the southeast United States discussed above is also accompanied by cooler temperatures in that region. Similar enhanced zonal flow over sub-tropical South America leads to above-normal temperatures along the west coast; as in North America, this signal is most extensive during its winter.

ENSO and Climate Variations

It is important to recognize that the ENSO teleconnections represent statistical averages over the last half-century, and the strength of these waxes and wanes on decadal timescales

for several reasons. For example, because tropical Pacific SSTs exert only a modest control on seasonal climate variations, random fluctuations of the teleconnections due to sampling alone can occur on multi-decadal timescales (Allan 2000; Diaz et al. 2001).

It has been noted elsewhere that tropical Pacific SST variations were weak during 1920–40 compared with 1980–2000 (Trenberth and Shea 1987; Allan et al. 1996; Allan 2000). Given that the strength of teleconnections increases almost linearly with the amplitude of tropical Pacific SST anomalies (e.g., Kumar and Hoerling 1998), a reasonable assumption is that stronger teleconnections will occur during decades when tropical Pacific SSTs exhibit larger interannual variance. An additional factor requires no change in ENSO temporal behavior per se, but involves slow, multi-decadal, changes in the climatological mean SSTs themselves. These can alter the atmospheric sensitivity to interannual variations in tropical Pacific SSTs because the teleconnections respond to the total, rather than to the anomalous, SSTs.

One plausible factor in this strengthening of ENSO teleconnections is a multi-decadal change in the life cycle of tropical Pacific SST anomalies during warm events (Trenberth 1984; Mantua et al. 1997). The strength of teleconnection patterns emanating from changes in tropical convection associated with ENSO variability differed considerably before and after 1976 (Diaz et al. 2001). The origin for this change is not known, and may merely reflect the stochastic behavior of the equatorial coupled system itself. Nonetheless, the relevancy for the teleconnection process is large because the warm-event life cycle since 1976 has become closely phased with the climatological annual cycle, and in particular the prolonged anomalous warming in spring of year +1 now coincides with the peak annual cycle SST warming.

In many areas where a significant ENSO modulation of precipitation is present, the strength of that teleconnection has varied over the past century. It is unclear to what degree the temporal variations of ENSO teleconnections in different regions are related. To the extent that there is a dynamical root to the changes observed in the past century, for example, due to changes in the ENSO SST forcing, then it is reasonable that changes in one region would be accompanied by changes in another.

Decadal scale patterns in tropical and north Pacific SSTs have been shown to correlate to decadal scale changes in the extra-tropical circulation, and associated temperature and precipitation patterns, particularly over North America. These changes have been statistically linked to different phases of a decadal-scale pattern of SST anomaly in the North Pacific known as the Pacific Decadal Oscillation (PDO) (Mantua et al. 1997); however, it is not clear what is cause and what is effect. One interpretation of recent modeling work on the connection between low-frequency changes

in tropical SST, ENSO, and decadal scale changes in the general atmospheric circulation suggest a complex interplay between the canonical ENSO system, the slow changes in SST in the Indo-Pacific over the last century, and long-term changes in the atmospheric circulation itself.

Endogenic and Exogenic Factors

Henry Bokuniewicz

School of Marine and Atmospheric Sciences, Stony Brook University, Stony Brook, NY, USA

Synonyms

Endogenetic; Exogenetic

Definition

Endogenic (or endogenetic) factors are agents supplying energy for actions that are located within the earth. Endogenic factors have origins located well below the earth's surface. The term is applied, for example, to volcanic origins of landforms, but it is also applied to the original chemical precipitates. Exogenic (or exogenetic) factors are agents supplying energy for actions that are located at, or near, the earth's surface or extraterrestrial. The term is commonly applied to various processes such as weathering, denudation, mass wasting, etc. In coastal science, these factors may be illustrated in two significant applications. One is the classification of coastlines and the other is the discussion of sea-level variations.

Factors in Coastline Classification

As early as 1885, Suess (as cited in Kennet 1982) described the fundamental difference between the coastlines of the Atlantic and those of the Pacific Ocean. This distinction is now the basis for classifying the world's coasts into three categories based on the endogenic processes of plate tectonics (Inman and Nordstrom 1971). Collision coasts are found at convergent plate boundaries such as along the west coasts of North and South America. They tend to be straight and

mountainous with narrow continental shelves. Marginal sea coasts, the second category, are protected from the open ocean by island arcs. An example would be the coast of Korea. Trailing-edge coasts are found on the interior areas of tectonic plates. When newly created, like the coast of the Red Sea, trailing-edge coasts appear similar to collision coasts; they are steep, lined by sea cliffs, and have a normal shelf. With age, however, they tend to have broad coastal plains, wide shelves, and low relief like the east coast of the United States.

The evolution of trailing-edge coasts corresponds to early concepts in geomorphology on the aging, or maturing, of continental margins by exogenic forces (Dietz 1952). Simply put, the continental crust is attacked by wave action and the continental margin shaped by the redistribution of marine sediment by coastal currents. Young, steep coasts are thereby replaced by the gently sloping surface of a thick wedge of coastal plain sediments. Turbidity currents and other elements of gravity-driven mass movements are then instrumental in the basic formation of the continental slope and rise. On a smaller scale, endogenic processes of faulting, volcanic, or other igneous structures provide other coastline types (Shepard 1963). These are typically erosional, rocky coastlines, referred to as erosional coasts in which the underlying geologic structure imposes the coastline pattern.

Coastal features formed by exogenic factors may be inherited or active. The surficial processes to which these coastal landforms owe their origin are no longer active. Coastlines formed by glacial action, such as fjords or drumlins, or drowned river valleys, are examples of inherited characteristics. Deltaic coasts, barrier islands, cusped forelands, tombolos, etc. are all features shaped by exogenic factors since they owe their origin to the active redistribution of sediment by waves and currents. Collectively such features are characteristics of accretional coasts, notwithstanding the fact that such coasts may have serious erosion problems.

Factors in Sea-Level Changes

Endogenic processes also control long-term eustatic sea-level changes. Deep-seated isostasy and the thermal structure of the oceanic lithosphere influence the relief of the ocean basin. Newly created seafloor stands in high relief being thermally expanded. With the passage of time, it cools, contracts, and subsides. As a result, changes in the rate of seafloor spreading and the total length of mid-ocean ridges changes the elevation of the oceanic platform, that is to say, the average depth of the ocean basin, and, consequently, the position of sea-level relative to the continents. A global drop in sea level of some 350 m at the end of the Cretaceous is attributed to the contraction of the mid-ocean ridge system, in part by the disappearance of spreading centers in the Pacific beneath North America.

Exogenic factors that control sea-level variations include seasonal cycles due to temperature variations, storm surges, or geostrophic adjustment of sea surface slopes by variations in the speed of coastal ocean currents. Anticipated sea-level changes, and other coastal impacts, due to global warming have exogenic origins. The current rate of eustatic sea-level rise is due predominantly to the combined effects of the liberation of water from the melting of glaciers and the thermal expansion of the surficial layer of the ocean.

Extraterrestrial Factors

The term “exogenic” is also applied to agents having their origins outside the earth such as solar radiation, comets, or meteorites. A collection of features that owe their origin to the impact of meteorites, such as coastal deposits of a tsunami resulting from the Cretaceous impact event, could be ascribed to this class of exogenic factors.

The Anthropocene

Although exogenic factors are usually driven by gravity or atmospheric forces, the extent of human impacts on the global environment make human activity an exogenic factor. Recognition of the global scale of human impacts on surficial processes worldwide is embodied as the “Anthropocene.”

Anthropogenetic factors of climate change, sea level rise, ocean acidification, changes in land-use, global freshwater demand, stratospheric ozone, and various biogeochemical cycles all impact the functioning of earth’s surficial systems.

Conclusion

The distinction between exogenic and endogenic factors provides the underlying direction in the search for causes of terrestrial phenomena and features. Of particular importance in the Anthropocene is the recognition of factors that human beings might manipulate, or have manipulated, to impact climate change or its consequences. While these are exogenic, for the most part, other factors are recognized as beyond the control of humankind but deserve monitoring for advanced warning of potential hazards.

Energy and Sediment Budgets of the Global Coastal Zone

Douglas L. Inman and Scott A. Jenkins

Department of Center for Coastal Studies, Scripps Institution of Oceanography, University of California, San Diego, La Jolla, CA, USA

The energy for the global coastal zone is primarily powered by solar irradiance and tides. The solar irradiance warms the earth’s surface unevenly, driving wind and current systems that redistribute heat and generate storms with rainfall and snow that erode landmasses. The erosion products of sediment and dissolved solids are carried to the sea by rivers and glaciers. Winds, waves, tides, and currents transport and redistribute sediment and sculpt coastal landforms.

Solar irradiance provides an energy flux of about 1.8×10^{14} kilowatt (kW) to the earth. About 2.5×10^9 kW of mechanical energy in windgenerated waves is incident on the world’s 440,000 km coastlines. Another 2.2×10^9 kW of tidal energy is expended in shallow seas. The total flux of mechanical energy of all kinds in shallow waters of the coastal zone is about 5.5×10^4 kW. Some of this energy is expended in coastal erosion and transport of the erosion products from the land, and the remainder drives frictional processes and is dissipated as heat. The erosion rate of land is about 6 cm/thousand years resulting in a flux to the sea of 5×10^9 ton/year dissolved solids and 20×10^9 ton/year particulate solids (1 ton = 1,000 kg).

Douglas L. Inman: deceased.

Introduction

The oceans respond to many different kinds of steady and impulsive forces applied at their boundaries with the atmosphere and seafloor. Although most energy in the nearshore waters comes from windgenerated waves and tidal currents, energy from a number of other sources such as internal waves and ocean currents may also be important locally.

One approach to understanding the relative importance of nearshore processes is to compare the sea's potential to erode the land with the land's potential to supply terrestrial erosion products. Such a comparison ultimately resolves itself into the balance between the budget of power in waves and currents and the budget of sediments available for transport. Of course, this balance varies widely from place to place, and even in the best-studied areas is but poorly understood. However, order of magnitude estimates can be attempted on a worldwide basis, and their consideration here gives some overall perspective for the relative importance of the driving forces that are operative in nearshore waters.

In a practical sense, the waters of the coastal zone can be considered as including the shallow seas and the waters covering the continental shelves of the world, an area of $29 \times 10^6 \text{ km}^2$, or about 5.5% of the surface area of the world and about 8% of the area of the world oceans (Table 1). The nearshore waters are bounded on the landward side by coastlines that total about 440,000 km in length, and to the seaward by the break in slope at the shelf edge (shelf break) marking the change from the relatively horizontal continental shelf to the steeper continental slope. The continental slopes are one of the striking geographic features of the earth and have a combined length of about 150,000 km.

Conventionally, the depth of the shelf break is taken as 200 m or 100 fathom, although in some localities the depth may be as great as 400 m. On a worldwide basis, the average

depth of the shelf break is about 130 m. The width of the shelf ranges from zero to over 1,300 km and averages about 74 km (Shepard 1963). Although having little geomorphic basis, international law defines *territorial seas* as usually extending seaward 12 nautical miles (22.2 km) beyond the coastline and an *exclusive economic zone* as usually extending 200 nautical miles (371 km) seaward.

Budget of Energy in Shallow Water

The current systems of the world's atmosphere and ocean are solar powered. The sun irradiates the earth with a total of about $1.8 \times 10^{14} \text{ kW}$, or an intensity of 1.37 kW/m^2 , the so-called solar constant. In terms of the rotating, spherical earth, this averages to about 342 W/m^2 of earth's surface. Of this amount about 30% is reflected and backscattered, 19% is absorbed by the atmosphere, and 51% is absorbed at the earth's surface (e.g., Gill 1982). Solar energy heats the earth's surface unevenly and generates winds. The oceans are relatively opaque to solar irradiance, so that the effect on the oceans is to stratify and stabilize the surface water. As a consequence, the ocean responds much more to wind, even though the intensity of thermal energy from the sun greatly exceeds the mechanical energy from the wind at the water's surface. Averaged over the earth's surface, the intensity of thermal energy absorbed is about 175 W/m^2 , while the sea surface stresses and pressures caused by a wind blowing 10 m/s expend about 1.3 W/m^2 . In contrast, the mean heat flow to the earth's surface from the interior is approximately 0.1 W/m^2 , and occurs mostly at the mid-ocean spreading centers (Pollack et al. 1993). Thus, it is the solar powered atmosphere and ocean currents together that maintain the earth's heat budget by accounting for a poleward transport of energy at the rate of about $8 \times 10^9 \text{ kW}$.

Studies of the energy budgets of the ocean and atmosphere (e.g., Webster 1994) show that the total energy content of the oceans ($\sim 160 \times 10^{25} \text{ joule (J)}$) is 1000 times larger than that of the atmosphere ($\sim 125 \times 10^{22} \text{ J}$). Because of greater mass and heat capacity, the oceans play a critical role in controlling and moderating weather and climate. However, in terms of the kinetic energy available for interacting with the oceans, the atmospheric kinetic energy ($\sim 6 \times 10^{20} \text{ J}$) is 200 times larger than that of the oceans.

The wind systems are the direct link between atmosphere and ocean and, through momentum exchange at the ocean's surface, expend kinetic energy at the rate of about 10^{11} kW (Malkus 1962; Newell et al. 1992). The prevailing wind systems cause all large bodies of water to have windward and leeward shores. The Pacific coasts of the Americas are in general windward coasts while the Atlantic seaboard is leeward coasts. The general wind flow is clockwise in the Northern Hemisphere around semipermanent, midlatitude areas of high pressure, for example, the north Pacific high

and the Bermuda high in the Atlantic Ocean. Circulation patterns in the southern oceans are essentially counterclockwise flowing mirror images of those in the Northern Hemisphere (Fig. 1).

Sea and Swell

The most intense wave action in all oceans results from cyclogenesis over the poleward-flowing, western boundary currents. These warm water jets carry equatorial heat to higher latitudes and produce strong temperature gradients that spin-up intense storms (Fig. 1). These boundary cyclonic events generate large, high-frequency *sea waves* along leeward shores and long waves that cross the ocean and appear as low-frequency *swell* on windward coasts. In the north Pacific, dry Siberian winds flowing over the warmer Kuroshio Current produce a series of cyclonic cold fronts that collectively have long fetches and generate the high waves for the Pacific coast of North America during the winter. These storms

produce swell when they are distant and sea waves as their tracks near the coast.

Long, low-frequency swell is typically absent from leeward coasts. Rather they are subject to periodic, intense sea waves from the poleward and easterly traveling storm fronts. The tracks for tropical (summer/fall) storms for the middle Atlantic seaboard of the United States essentially follow the Gulf Stream, while the extratropical (winter/spring) tracks take a more easterly course. In midlatitudes the tracks are channeled between the coast and the perimeter of the Bermuda high. This channel is sometimes known as the Atlantic seaboard cyclone track (e.g., Klein and Winston 1958). In the vicinity of Cape Hatteras, the highest waves from both extra- and tropical storms are from the northeast. The storm tracks are offshore and generally parallel the coast, so that the counterclockwise flowing winds in the northwest quadrant of the cyclone (winds blowing from the northeast) are the strongest and have the longest fetch (e.g., Dolan

Energy and Sediment Budgets of the Global Coastal Zone, Fig. 1 Prevailing winds and storm tracks for the world oceans

et al. 1990). Thus, prevailing waves along the windward coasts and the strongest cyclonic sea waves along the leeward coasts both have net components toward the equator. As a consequence, there is a worldwide tendency in midlatitudes (20° – 45°) for the net wave-induced littoral transport of sand to be toward the equator.

A three meter-high surface wave at sea transmits 100 kW for every meter of wave crest, or 100 MW/km. Since wave energy increases as the square of wave height, most coastal energy is from high waves during storms, particularly storms of long duration. For example, the northeast storm of March 1989 along the Outer Banks of North Carolina had average deepwater wave heights of 3 m (Dolan et al. 1990). These were not unusually high waves, but they persisted for 115 h and had a power expenditure of 11,500 kilowatt hours per meter (kWh/m) of coastline. The average energy flux of waves on the Outer Banks is about 2 kW/m, which sums to a yearly total of 17,500 kWh/m (Inman and Dolan 1989). Thus this one storm had a power expenditure (and sand transport potential) equivalent to 66% of that for the average year.

Data of instrumented buoys and light vessels in the North Atlantic and North Pacific all show that wave heights have increased significantly and continuously during the past 25 years (e.g., Graham and Diaz 2001). The North Atlantic data show that the average annual (root-mean square) wave height has increased about 2% per year between 1962 and 1986. Over the 24-year period (1962–86) the range in average annual *significant wave* ($\sqrt{2}$ times root-mean square) height at Seven Stones Light Vessel off Lands End, southwest England, ranged from 2.2 to 2.9 m with an annual increase of 3 cm/year. The “50-year return value” ranged from 12 to 18 m with an increase of 20 cm/year (Carter and Draper 1988). Data from six buoys between latitude 34° and 56° in the eastern North Pacific show similar increasing trends over the period 1975–99. The annual average significant wave height increased on average about 2 cm/year, ranging for the six buoys from 0.4 to 4.2 cm/year (Allen and Komar 2000).

A preliminary estimate of global wave energy can be attempted from the data obtained from instrumented buoys and weather stations in the North Pacific and North Atlantic. The measurements for the eastern North Pacific cover the 25-year time interval from 1975 to 1999 (Allen and Komar 2000). Over this period, the average annual (root-mean square) wave height increased progressively from about 1.6 to 1.9 m, generating a landward wave energy flux that ranged for these average waves from about 93×10^6 to 131×10^6 kW over the same period. Thus, the wave height increased about 20% while the corresponding energy flux increased about 40%. Similar wave conditions and wave height increases over about the same period were observed for the eastern North Atlantic Ocean (Carter and Draper 1988). If it is assumed that the energy partitioning between

periods of calm and storm results in an energy flux twice that estimated from the average annual wave height (i.e., the significant wave assumption), then the total annual energy flux over the 25-year period in the North Pacific becomes about 190 and 260×10^6 kW with an average for the period of about 230×10^6 kW for this 30° – 60° latitude portion of the windward coast of North America.

When the energy flux of 260×10^6 kW for the North Pacific Ocean is extrapolated to the world oceans, the total wave energy flux to the global coastline becomes 2.5×10^9 kW (Table 2, footnote a). This is in agreement with earlier estimates (e.g., Inman 1973) and gives an average energy flux of 5.7 kW/m to the 440,000 km of world coastline.

What is known about wave climate intensity suggests that windward coasts of oceans in the Northern Hemisphere are in phase with each other during El Niño and La Niña events and out of phase with lee coasts. In terms of decadal climate patterns, which are alternately El Niño or La Niña dominated, the prevailing wind stress and swell directions in the Northern and Southern Hemisphere appear to be out of phase (Trenberth and Hurrell 1994; Chao et al. 2000). For example, during the La Niña dominated climate of the third-quarter of the twentieth century, waves from the southern ocean appeared as “southern swell” along the California coast. Southern swell was absent from the California coast during the previous quarter of the century and again disappeared during the last quarter century (Inman and Jenkins 1997). This is because of a global realignment in predominant storm tracks with changes in the phase of Pacific Decadal Oscillation (PDO), where El Niño storm tracks tend to be more zonal than those of La Niña storms.

Energy and Sediment Budgets of the Global Coastal Zone, Table 2 Estimates of the flux of mechanical energy in the shallow waters of the world in units of 10^9 kW

Wind-generated waves breaking against the coastline ^a	2.5
Tidal currents due to surface tides on shelves and in shallow seas ^b	2.2
Currents due to internal waves and tides over shelves ^c	0.5
Large-scale ocean currents in shallow seas ^b	0.2
All other sources	0.1
Total	5.5

^aAssuming the average energy flux for the six instrumented NOAA buoys in the eastern North Pacific (Allen and Komar 2000), proportioned over 30° – 60° north latitude, is 230×10^6 kW (see text) and that for the 0° – 30° portion of the eastern North Pacific is one-half, and that for the leeward ocean coasts is one third that of the windward coasts, giving a total for the coasts bordering the North Pacific Ocean of 460×10^6 kW. The global flux is assumed to be equivalent to that from five and one-half oceans like the North Pacific Ocean (i.e., North and South Pacific Oceans, North and South Atlantic Oceans, Indian Ocean, and one-half “ocean” equivalence for all marginal seas)

^bInman and Brush (1973)

^cConservative estimate from Wunsch and Hendry (1972)

Consequently, the long waves of El Niño storms do not generally propagate out of the hemisphere in which they were generated. Conversely, the frontal circulation of La Niña storms is more meridional, generating waves that traverse latitude. Therefore, the Northern Hemisphere beaches are usually affected by Southern Hemisphere swells only when the Southern Hemisphere is in a La Niña dominated climate pattern.

Studies of windfields and pressure gradients indicate that the increase in wave heights in the eastern North Atlantic during the last quarter of the twentieth century resulted from intensification of the pressure gradients between the Iceland low and the Azores high which could be related to climate change associated with the North Atlantic Oscillation (NAO) (Kushnir et al. 1997). It is likely that some of the increase in wave intensity in the eastern North Pacific Ocean was associated with the PDO and increased sea surface temperatures during the last quarter of the century. However, it is unclear what portion of these increased wave heights in the North Atlantic and North Pacific oceans are also associated with global warming (Graham and Diaz 2001). If the increases are mainly due to decadal oscillations, they suggest that decadal climate lead to $\pm 30\%$ changes in wave climate (see entry on “► Climate Patterns in the Coastal Zone”).

Tsunamis

The most impressive waves in the sea are those generated by submarine earthquakes, landslides, and volcanic explosions (e.g., Van Dorn 1987). These waves, called *tsunamis*, are well known because of the loss of life and great damage to coastal structures associated with their passage. Of the many types of surface waves, tsunamis contain the highest instantaneous power surges. They are reported to have caused runup to heights as great as 50 m above sea level in modern times and to greater heights in ancient times. The explosion and collapse of the volcanic island of Thera (Santorini) about 1400 bc is thought to have caused a tsunami, about 11 m high at Crete (Yokoyama 1978), that may have ended Minoan maritime supremacy. The largest, well-documented tsunami was associated with the explosion and collapse of Krakatoa volcano in Sunda Strait between the Indonesian Islands of Java and Sumatra in August, 1883. The energy of the explosion is estimated to have been 2×10^{18} J (500 megatons of TNT) and it ejected 18 km^3 of material into the atmosphere (e.g., Simkin and Fiske 1983). The resulting tsunami was estimated to be nearly 40 m in height; it drowned 36,000 people and destroyed 5,000 ships. One ship, the *Berouw* was carried 2 km inland on Sumatra where it remains today. The tsunami was observed on tide gauges throughout the world, and dust from the explosion covered the entire world causing brilliant sunsets for many years.

Detectable tsunamis have occurred about once a year. However, truly large tsunamis with energy content as

high as 5×10^{15} J occur only about five times per century. Averaged over long periods, tsunamis would generate an energy flux of about 1×10^5 kW. Thus, because of their relative infrequency, these catastrophic waves contribute little to the worldwide budget of power.

Tides

The gravitational forces of moon and sun provide the driving forces for the ocean tides, with the moon's tide generating force being about twice that of the sun. The main lunar (semidiurnal, M_2) tide with a period of 12.42 h is the principal world tide; however, the interaction between lunar and solar forces provides a variety of tide-generating constituents. Locally, tidal amplitudes are determined in part by the interactions of the propagating oceanic tidal bulge with the shape of the ocean basin, favoring oscillations that are harmonics of the tidal forcing and the basin dimensions. The dominant tidal oscillations are usually referred to as *semidiurnal* (twice daily), *diurnal* (once daily), and *mixed* tides that are combinations of the two, such as those along the Pacific coast of the Americas.

The ocean surface tides, having wavelengths that are very long compared with the depth of the ocean, produce some motion even in the deepest water. However, this motion is usually only a few centimeters per second so that the energy dissipation by tides against the deep-sea bottom is slight. The principal tidal dissipation results from the flow of strong tidal currents in shallow areas, such as the Bering Sea and the Argentine shelf. One of the more impressive tidal coastlines occurs in Argentina. The tidal wave travels eastward through Drake Passage and then northward where it shoals over the broad Argentine shelf, attaining spring ranges of nearly 15 m at Rio Gallegos. From the southeastern tip of Tierra del Fuego to Bahia Blanca, a distance of 2,800 km, the tidal range is mostly in excess of 6 m.

“Tides are unique among natural physical processes in that one can predict their motions well into the future with acceptable accuracy without learning anything about their physical mechanism” (Cartwright 1977). Their prediction from tide gauge records has been possible since Darwin formulated the rules of harmonic tide prediction in 1883. But, prediction from harmonic constituents can be in error when changing wind fields and warm water associated with El Niño events raise and lower sea level by 30 cm and more.

The energy dissipated by various kinds of tidal currents against the shallow sea bottom is one of the major factors that causes the rotational deceleration of the earth. Much of our present knowledge of this dissipation results from investigations by geophysicists into the possible causes of the deceleration in the earth's rotation (Jeffreys 1920, 1970; Munk and MacDonald 1960). Tidal dissipation causes a lag in the tidal bulge of the Earth relative to the rotation of the earth-moon system. This bulge exerts a torque that results in a decrease in both the earth's rotation rate and in the lunar orbital velocity.

From telescopic observations of sun and moon over the previous two and one-half centuries, Spencer Jones (Munk and MacDonald 1960) determined that the moon's deceleration was $22.4 \text{ arcsec/century}^2$. This deceleration would be associated with an energy dissipation in the atmosphere, oceans, and solid earth of about $2.7 \times 10^9 \text{ kW}$. More recently, measurements of the change in the moon's semimajor axis using laser ranging techniques show that the frictional energy dissipation due to the M_2 tides is $3.1 \times 10^9 \text{ kW}$, giving a dissipation rate due to the solar and lunar tides of about $4.0 \times 10^9 \text{ kW}$ (e.g., Dickey et al. 1994). The allocation by process for these revised dissipations of tidal energy is not yet understood. The best estimates for the lunar tidal dissipation in shallow seas is that of Miller (1966). He used the method of energy flux into shallow seas, rather than the less accurate method of summing the energy loss due to frictional drag on unit area of the bottom. His value of $1.7 \times 10^9 \text{ kW}$ for lunar tidal energy dissipation, when corrected for the solar tidal flux, gives a total energy dissipation for shallow seas of $2.2 \times 10^9 \text{ kW}$ (Table 2).

Internal Waves

Internal waves are water oscillations that occur within the various density layers beneath the ocean surface. It appears that far more energy is transformed into internal (baroclinic) waves than was previously thought. The vertically integrated energy over the deep sea is typically about $4 \times 10^{-3} \text{ J/m}^2$ (e.g., Garrett and Munk 1979). Mechanisms generating internal waves include direct coupling between ocean surface waves and the density layers beneath the surface, scattering due to seafloor roughness (Cox and Sandstrom 1962), and generation by impingement of deep-sea tides on the slopes of the continental shelves and submarine canyons (Rattray et al. 1969).

Cox and Sandstrom (1962) found that internal waves were coupled to surface waves and estimate that the rate of conversion of tidal energy into internal wave energy in the Atlantic Ocean is roughly between 6 and 69% of the power of the surface tide. From this, Munk and MacDonald (1960) estimate that the conversion of energy from surface to internal modes on a global scale may be about $1.5 \times 10^9 \text{ kW}$. Most internal wave energy is contained in the areas of deep ocean, but some of the energy travels into shallow water and is dissipated against the sea bottom. Winant (1974) estimated that the dissipation due to runup of breaking internal waves and surges on the shelves of the world may range between 2×10^5 and $2 \times 10^7 \text{ kW}$.

Wunsch and Hendry (1972) measured currents from an array placed on the continental slope off Long Island, New York, and concluded that the onshore energy flux of internal waves was 6 W/m . Assuming this to be a typical value, they estimated that the worldwide onshore flux of energy would be about $0.7 \times 10^9 \text{ kW}$. A value of about $0.5 \times 10^9 \text{ kW}$ for the energy dissipation by internal waves over the world's shelves appears to be a reasonable estimate (Table 2).

Ocean Currents, Large and Small

The kinetic energy associated with large-scale ocean currents is very large compared with the energy in surface waves and tidal currents. Stommel (1958) estimates that the average kinetic energy of currents in the North Atlantic Ocean is about $2 \times 10^{17} \text{ J}$. Flows such as the equatorial and Antarctic Circumpolar currents transport water at rates of 50–200 Sv (Sverdrup = million cubic meter per second). Even the relatively small California current transports about 12 Sv, a discharge that is greater than that of all the rivers and streams in the world. In addition to the surface currents, the world ocean has a surprisingly large circulation of deep and bottom water estimated to be 50 Sv (e.g., Schmitz Schmitz 1995).

Intense western boundary currents, such as the Gulf Stream, develop instabilities with horizontal waves or meanders. These meanders form large loops that may close or pinch-off, forming circular eddies or rings. These *mesoscale eddies* are typically 100 km and more in diameter, and since they are in cycloidal balance, conservation of angular momentum causes them to persist for many months to a year or so, as they move thousands of kilometers away from the main current. Eddies that breakoff from the poleward side of the currents have warm-cores and cyclonic rotation, whereas those shed from the equatorial side have cold-cores and anticyclonic motion (e.g., Gill 1982). The details of the global distribution of the energy in mesoscale eddies is not well known except for satellite observations of western boundary currents. The effects of mesoscale eddies on the continental shelves is poorly understood, although it is known that shelf eddies are associated with wind changes and with coastal promontories (e.g., Davis 1985).

While the flow of major ocean currents is predominantly in deepwater, their boundaries overlap the continental shelves, and the currents dissipate some of their energy against the shallow sea bottoms. For example, the Guiana (North Brazil) Current, with a volume discharge of about 29 Sv, flows with velocities up to 1 m/s over the $0.5 \times 10^6 \text{ km}^2$ of shelf off the coastlines of the Guianas and northern Brazil (e.g., Fratantoni et al. 1995). The Falkland Current flows with velocities of 25–50 cm/s across the $1 \times 10^6 \text{ km}^2$ of shallow shelf off Patagonia. If the Guiana Current averages 50 cm/s and the Falkland Current averages 25 cm/s, they would dissipate energy at the rate of 0.13×10^9 and $0.03 \times 10^9 \text{ kW}$, respectively. Therefore, it seems likely that the worldwide dissipation of energy from the flow of ocean currents in shallow water may be about $0.2 \times 10^9 \text{ kW}$ (Table 2).

Other Sources

In addition to generating the ocean's waves, atmospheric winds, and pressures have important local effects nearshore. Pressure fronts generate shelf seiche, and the combination of pressure and wind stress on the water's surface produces local anomalies in sea level that induce circulation of water over the

shelf and in submarine canyons. Shelf seiche up to a meter in height or more are common along the Argentine coast (Inman et al. 1962), while the sea level anomalies associated with storm surges may exceed 4 m for severe storms (Pugh 1987). Also, winds blowing over the coastal zone dissipate energy on beach and sand dunes. On a worldwide basis, this dissipation may be about 1×10^7 kW, and because of the prevalence of sea breeze and other onshore winds, results in a net inland transport of beach sand.

From the foregoing discussion, it appears that the total flux of mechanical energy in the shallow waters of the world is about 5.5×10^9 kW (Table 2). Dissipation and work by one process or another occurs over the entire shelf. The wind-generated surface waves expend their energy primarily near-shore, especially in the breaker zone, while tidal and other ocean currents and internal waves dissipate energy mostly over the outer portions of the shelf. Internal waves, edge waves, shelf seiche, and local winds may produce water motion over the continental shelf and submarine canyons.

Budget of Sediment

The coastline is the junction of the realms of terrestrial erosion and marine deposition. Thus, it is the unique singularity between air, land, and sea, and the coastline is the critical

datum for dynamical geology. In 1955, James Gilluly calculated that sediment is now being carried across this boundary at a rate great enough, in the absence of mountain building, to “erase all the topography above sea level in less than 10 million years . . .,” a very short time on the geological timescale. Thus, the supply of sediment associated with runoff from the continents is large, and it has increased during the past 10 million years due to climate variability, especially during the Pleistocene and more recently due to human intervention. The principal sources of beach and nearshore sediments are the rivers that bring large quantities of sand directly to the ocean, the sea cliffs of unconsolidated material that are eroded by waves, and material of biological origin such as shells, coral fragments, and skeletons of other small marine organisms (Fig. 2). Also, waves may transport onshore relict sands that were deposited along the inner shelf during lower stands of the sea (e.g., Inman and Dolan 1989).

Sediment yield increases with the relief of the drainage basin and with decrease in basin size, factors that enhance the sediment flux of small rivers along mountainous coasts (Inman and Jenkins 1999). Climate, rainfall, and type of geologic formation are also well-known factors in determining sediment yield. Maximum yield occurs for basins in temperate climates that receive an annual rainfall of about 25–50 cm, and decreases for precipitation rates either above or below this maximum (Langbein and Schumm 1958).

Energy and Sediment Budgets of the Global Coastal Zone, Fig. 2 Schematic diagram of budget of energy dissipation in nearshore waters, and the runoff of water and sediment from the land (after Inman 1973). (Data from Tables 1, 2, and 3)

In arid climates, the occasional flash floods transport large volumes of sand (Fig. 3).

Man's intervention in natural processes is accelerating erosion rates, perhaps by a factor of about two on a global scale (Milliman and Syvitski 1992; Vitousek et al. 1997). Significant anthropogenic effects began as early as 9,000 years ago with deforestation and the spread of agriculture from the "Fertile Crescent" (e.g., Heun et al. 1997). Man's intervention has accelerated in this century with increased deforestation, expansion of mechanized agriculture, proliferation of dams (Meade 1996), and since World War II with extensive urbanization of coastal lands particularly in central and southern California. Urbanization decreases erosion locally, but accelerates streambed erosion in response to the greater frequency and magnitude of peak streamflow due to runoff from impervious urban surfaces (e.g., Trimble 1997).

The effects of changing climate and sea-level rise have been studied extensively on a glacial/interglacial timescale (e.g., Hay 1994) and during the Holocene on a millennial scale (e.g., Bond et al. 1997). The effect of decadal scale climate changes on the sediment flux of the 20 largest streams entering the Pacific Ocean along the central and southern California coast was studied by Inman and Jenkins (1999). The annual streamflow ranged from zero during dry years to a maximum of $1.1 \times 10^9 \text{ m}^3/\text{year}$ for the Santa Clara River in 1969 with an associated suspended sediment flux of $46 \times 10^6 \text{ ton}$. Trend analyses showed that El Niño/Southern Oscillation (ENSO) induced climate changes recur on a multidecadal

timescale in general agreement with the Pacific/North American (PNA) climate pattern: a dry climate extending from 1944 to about 1968 and a wet climate extending from about 1969 to 1998. The dry period is characterized by consistently low annual river sediment flux. The wet period had a mean annual suspended sediment flux about five times greater, caused by strong El Niño events that produce floods with an average recurrence of about 5 years. The sediment flux of the rivers during the three major flood years averaged 27 times greater than the annual flux during the previous dry climate (see entry "► Climate Patterns in the Coastal Zone").

The effects of climate change are superimposed on erodibility associated with basin geology. The sediment yield of the faulted, overturned Cenozoic sediments of the transverse ranges of California is many times greater than that of the coast ranges and peninsular ranges. Thus the abrupt transition from dry to wet climate in 1969 brought a suspended sediment flux of 100 million tons to the ocean edge of the Santa Barbara Channel from the rivers of the Transverse Range, an amount greater than their total flux during the preceding 25-year dry period. These alternating dry to wet decadal scale changes in climate are natural cycles that have profound effects on fluvial morphology, engineering structures, and the supply of sediment.

Cliff erosion probably does not account for more than about 5% of the material on most beaches. Wave erosion of rocky coasts is usually slow, even where the rocks are relatively soft shales. On the other hand, erosion rates greater than 1 m/year are not uncommon in unconsolidated sea cliffs and

Energy and Sediment Budgets of the Global Coastal Zone,

Fig. 3 Streams carry erosion products from the land to the sea; El Moreno, Gulf of California, Mexico

dunes as found on trailing-edge coasts such as the east coast of the United States.

Following initial deposition at the mouths of streams entering the ocean, much of the sand-size portion of terrestrial sediments is carried along the coast by waves and wave-induced longshore currents. The sand carried by these longshore currents may be intercepted by submarine canyons that cut into the continental shelf and divert the sand into deeper water offshore. Since submarine canyons occur along most coasts, except those bordered by shallow seas, they probably account for most of the sediment lost into deepwater from the nearshore. Notable among the major sediment transporting submarine canyons of the world are Cap Breton Submarine Canyon on the Atlantic coast of France; Cayar and Trou Sans Fond, and Congo Canyons on the Atlantic coast of Africa; the Indus and the Ganges Submarine Canyons in the Indian Ocean; and the Monterey Submarine Canyon on the Pacific coast of North America. Observations by H.W. Menard (1960) suggest that most of the deep sediments on the abyssal plains along a 400 km section of the California coastline are derived from two submarine canyons: the Delgada Submarine Canyon in Northern California and Monterey Submarine Canyon in central California. These canyons cut the continental shelf almost to the shoreline, and consequently they trap and divert an estimated sediment volume of about $1 \times 10^6 \text{ m}^3/\text{year}$ (see entry on “► Littoral Cells”).

Traditionally, geologists have estimated long-term erosion and deposition rates from the amount of material deposited during geological time. Such estimates give erosion rates varying from about 1 to 4 cm per thousand years (cm/kyr) for drainage basins of moderate relief to as high as 21–100 cm/kyr for the Himalaya Mountains (e.g., Gilluly 1955). Assessment of the volume of sedimentary material on the continental United States and in its adjacent seafloors indicates that the average erosion rate of the United States during the past 600 million years was 3–6 cm/kyr (Gilluly et al. 1970).

An increasing number of measurements of river discharge have provided an independent estimate of contemporary erosion rates of the land. The importance of large rivers in transporting the denudation products of the continents to the sea has been known since Lyell (1873) described the flux of sediment into the Bay of Bengal from the Ganges and Brahmaputra Rivers. Since then the contributions from large rivers have been updated and summarized in many studies (e.g., Garrels and MacKenzie 1971; Inman and Brush 1973; Meade 1996) with estimates of the total flux of particulate solids to the ocean of about $16 \times 10^9 \text{ ton/year}$. The importance of small rivers to the global budget of sediment was first documented by Milliman and Syvitski (1992). They showed that small rivers (drainage basin $<10,000 \text{ km}^2$) cover only 20% of the land area but their large number results in their

Energy and Sediment Budgets of the Global Coastal Zone, Table 3 Estimate of the natural runoff of fresh water and solids from the continents into the oceans and coastal waters of the world

Discharge of water into the oceans from all rivers ^a	$1.3 \times 10^6 \text{ m}^3/\text{s}$
Flux of dissolved solids ^b	160 ton/s
Flux of particulate solids ^b	630 ton/s
Flux of particulate solids from sea cliff erosion ^c	$>2 \text{ ton/s}$
Flux of eolian particulate solids ^d	14 ton/s
Average erosion rate of land ^b	6 cm/kyr

^aAverage value ($1.1 \times 10^6 \text{ m}^3/\text{s}$) from Turekian (1971), Alekin and Brazhnikova (1961), and Holeman (1968) updated in proportion to increase in particulate solids from 530 to 630 ton/s

^bAssuming that continental rock of density 2.7 ton/m^3 erodes to form 20% dissolved load and 80% solid particulate load. Assuming flux of particulate solids is 630 ton/s (Milliman and Syvitski 1992)

^cEmery and Milliman 1978

^dWindblown dust, volcanic and forest fire ash (Prospero and Carlson 1981; Rea 1994; Prospero et al. 2002)

collectively contributing much more sediment than previously estimated, increasing the total flux of particulate solids to about $20 \times 10^9 \text{ ton/year}$ (630 ton/s) by streams and rivers (Table 3).

Balance of the Budgets of Power and Sediment

The global flux of erosion products from the land to the sea include 160 ton/s dissolved solids and 630 ton/s particulate solids (Table 3). The dissolved solids are incorporated into the $1.3 \times 10^6 \text{ m}^3/\text{s}$ flow of “fresh” water as added mass. Most of the particulate solids carried by stream-flow are fine silt and clay size material that move as suspended load and washload. The remaining solids are sand and coarser material that move mostly as bed and suspended load. Once the stream discharges into the sea, there are significant differences in the transport paths of the suspended and bedload sediment. Most of the fine suspended sediment moves with the river water and flows out over the sea as a spreading turbid plume, and the sediment, which is subject to flocculation and ingestion by organisms, is eventually deposited in deeper water. The coarser bedload material remains near the river mouth as a submerged sand delta and is later transported along the shore by waves and currents to nourish the downcoast beaches. The few reliable measurements of bedload indicate that it is ca. $\leq 10\%$ of the total load in large rivers but, in smaller, mountainous streams, may be considerably more (Richards 1982; Inman and Jenkins 1999).

It is of interest to compare the global fluxes of energy and sediments into the coastal waters of the world (Fig. 2). Since energy provides the capacity for doing work, the flux of energy associated with waves and currents is a measure of their potential to transport sediment. About one-half ($2.9 \times 10^9 \text{ kW}$) of the total flux of mechanical energy is associated with currents of various types, internal waves,

and turbulence, and this flux acts primarily upon the fine particulate solids that flow out over the ocean surface. The remaining energy (2.5×10^9 kW) is from ocean surface waves and works primarily on sand size solids that are deposited in shallow water. About 85% (535 ton/s) of the particulate solids are fine material, while about 15% (95 ton/s) are sand and coarser.

Waves move sand on, off, and along the shore. Once an equilibrium beach profile is established, the principal transport is along the coast. Theory and field measurements show that the littoral transport rate of sand along a beach is proportional to the energy flux of the incident waves, where the proportionality is a function of the direction of wave approach relative to the shoreline. If 10% of the world's estimated annual wave power at the coast (0.25×10^9 kW) is available for transporting sediment (i.e., the wave breaker angle is about 5°), the waves have the potential to transport the entire sand size load of solids in the world's streams (95 ton/s), a distance of 750 km along the coast each year. Thus, even under the inefficient coupling that exists in nature, it is apparent that the potential for sediment transport in nearshore waters is large.

Coastal Geomorphology

Literally, the title “geomorphology” comprises earth, shape and science with global aspects in that order. The study of earth science, from the strictly biblical concept of evolution to modern applied geomorphology, has been a long process in itself. In a generic term, geomorphology is indisputably a part of geology, but in institutional affiliation it has been a course in geography in almost all countries around the world. Coastal engineers have also contributed to its development in more recent time. Traditional geomorphology is concerned with the local landforms on the earth's surface and their processes over time. Coastal geomorphology, as a branch within the traditional geomorphology, is a relatively new discipline. It explores the relationship between coastal landforms and their processes affected by factors associated with climatology, oceanography, fluid mechanics, sedimentation, and geophysics.

Before the World War II, geomorphology – including coastal geomorphology – was largely Davisian, based on the concept of cyclic development and erosion, and of Johnsonian, in which the details in short-term coastal changes were ignored. Both approaches considered only the changes in vast stretches of time and space, and were once regarded as a “rather academic and, literally useless approach to coastal geomorphology” (e.g., Pethick 1986, p. 235). Although these concepts had suffered a major change during the War, their influence can still be traced.

Beginning in the 1940s, detailed work and examples of applied coastal geomorphology have emerged. By the 1950s, the approach had become process-oriented. This advanced further, especially in the 1970s and 1980s. Since then, numerous reports have become available resulting from the work carried out by coastal engineers on various coastal problems around the world.

Between the 1950s and 1980s, another almost universal approach taken by coastal geomorphologists was to attempt

a classification of coastal landforms – to recognize and describe coastal features. During this period, some major classifications on coasts were: (1) *submerged, emerged, and neutral* coasts due to past sea-level variations, (2) four regional types based on plate tectonic theory, (3) *primary* and *secondary* coasts based on the influence due to terrestrial agency or marine processes, (4) *high, moderate, and low-energy* beaches, (5) *east coast* and *west coast* environment depending on the relative location of the landmass, and (6) *storm* versus *swell* wave environments based on the level of wave energy inputs. However, applications of coastal geomorphology to stabilize eroding beaches were scarce.

Despite the diversity of these technical classifications, it is obvious that many physical features, in terms of the material and the types of physiographic units, can readily be identified along the ocean's edge. These include cliffs, rocky coasts, gravel beaches, sandy beaches, estuaries, deltas, lagoons, coral reefs, salt marshes, muddy fields, and mangrove swamps. For the sandy beaches, notable forms are beach cusps, salients and tombolos, spits, barrier islands, river mouth bars, straight beaches, and especially, curved or headland-bay beaches. These distinct landforms are produced by variable interactions due to the prevailing oceanographical and meteorological factors, as well as the geology of the physiographic units. Davies (1980) has demonstrated a global viewpoint between the orientation of a sandy beach and the direction of the persistent swell waves, resulting from the global wind system. Unfortunately, many basic textbooks in coastal geomorphology and engineering have continued to handle the beach processes at a local level without mentioning its global ramifications. Coastline curvature has been cited in some texts, but no further studies were made on its usage.

Geographers have been attracted by the similarity in the shapes and profiles of various landforms in order to find an appropriate mathematical expression to fit these shapes. This may be seen in the classical examples found in hill slopes, glacial valleys, and the longitudinal profiles of rivers. Researches on coastal landforms have produced a parabolic equation for equilibrium beach profiles (Dean 1991) and a logarithmic spiral equation for the planform of headland-bay beaches (Yasso 1965). The latter was widely accepted by geographers and engineers since its inception, until Hsu and his co-workers critically assessed it in the late 1980s. Summary of the development in bay beaches and its applications for shore protection can be found in Silvester and Hsu (1993, 1997).

Headland-Bay Beaches

The coastline along the boundary between the land and the sea may be either straight over a large length or curved in plan separated by headlands, natural or man-made. The

curved beaches are aesthetically beautiful and much more stable, compared with their straight counterparts. They may be fully exposed to waves, partially sheltered or fully protected by natural headlands or engineering structures.

General Characters of Headland-Bay Beaches

Of the curved beaches, some may be curved gently, others more indented, or with secondary features along its length. This unique geomorphic feature is ubiquitous not only on oceanic margins, but also on coasts of enclosed seas, lakes, and river foreshores. The bay beaches formed between natural headlands on the coasts can be easily identified on nautical charts, maps, aerial photographs, remote-sensing images, and even in travel brochures. They also appear downcoast of groins, and as salient or tombolo in the lee of protruding headlands, detached (offshore) breakwaters, and breakwaters for harbors. These curved beaches are found in various shapes and sizes, in relation to the prevailing waves and natural outcrops or headlands. The curved planform is produced by the persistent swell waves diffracted from the tip of a headland, combined with wave refraction and a nearshore current circulation system in the lee of the headland.

The curved or embayed beaches have attracted numerous names (Silvester and Hsu 1993), such as zeta curved bays, half-heart shaped bays, crenulate shaped beaches, logarithmic spiral beaches, curved or hooked beaches, headland-bay beaches, pocket beaches, and offset coasts. Despite their richness in existence and variety in names, stability of bay beaches was not fully tested by geographers and coastal engineers.

Since sandy beaches are constructed by persistent swell waves, their high-tide shoreline orientations are expected to align with the crest lines of these waves. Consequently, a series of asymmetrically curved bays can be found in many places. For example, they can be observed from Sydney to Fraser Island in eastern Australia, from Ilha de Santa Catarina to Rio de Janeiro in Brazil, and in other places. In these regions, the zeta shaped beaches have curved southern ends where they display a lower berm with finer sand particle and less steep beach faces than their straighter and more exposed northern ends. The consistency of coastline indentation and orientation can also be found in other continents around the world. It has taken some decades for this early recognition of bay shapes to become useful for stabilizing beaches in erosive conditions (Silvester 1979).

Silvester (1960) has questioned whether a bay beach is a stable physiographic feature. He believed that the orientation of the bay beaches is nature's method of balancing wave energy and load of sediment transport. In this manner, beaches have been maintained in position for tens, or even hundreds of years. The orientation of these bays also serves as an excellent indicator of the direction of net sediment movement along the coast. This macroscopic view of the coast

Engineering Applications of Coastal Geomorphology,

Fig. 1 Headland bay beaches in dynamic and static equilibrium

imposed by nature is an integrated part of the coastal geomorphology, in addition to the microscopic view of wave kinematics and sediment movements in the marine environment.

Before the stable bay shapes can be applied for useful purpose, its planform has to be quantified and its stability assessed. In geomorphic term, the stability of a bay beach (Fig. 1) may be in *static equilibrium* or *dynamic equilibrium*, or even *unstable*. A bay beach is: (1) stable and in *static equilibrium*, if the littoral drift is negligible or supply from upcoast is nonexistent, or (2) stable but in *dynamic equilibrium*, when the littoral drift is still being supplied from upcoast and/or from sources within the bay, or (3) *unstable*, implying potential retreat due to imbalance of sediment input and output. While sand supplied to the system is balanced by that which can be removed by oblique waves, a bay beach can remain in place for decades in dynamic equilibrium. However, this is a rare case today. On the other hand, should supply decrease, due to various reasons to be discussed later in "Causes of man-made erosion," the high-tide shoreline will recede toward the static equilibrium shape, which is the final limit without the impediment of shoreline protection structures.

Three major mathematical expressions have been proposed to fit the planform of bay beaches since 1940s. They are: (1) the logarithmic spiral equation suggested by Krumbein (1944) and quantified by Yasso (1965), (2) the parabolic equation for bays in static equilibrium given by Hsu and Evans (1989) and later reassessed by Silvester and Hsu (1993), and (3) the hyperbolic-tangent equation suggested by Moreno and Kraus (1999). These empirically derived equations have different coordinates systems and origins, and controlling parameters related to bay orientations.

With a computer, all three methods can be applied to fit the planform of any bay beach (Moreno and Kraus 1999). But there are some important differences, especially, in the recognition of the point of wave diffraction, the location of

the coordinates origin, and beach stability requirement. The log-spiral and hyperbolic-tangent shapes have some drawbacks. First, their coordinate origins do not coincide with the tip of the headland (e.g., the point of wave diffraction). Second, these methods do not address the issue of beach stability or their equations were not produced from bays known in static equilibrium. Third, these two methods do not provide the resultant beach parameters, such as radii and angles, to ease potential applications. As such the log-spiral and hyperbolic-tangent forms cannot determine the effect of sheltering and future extension of any existing headland, or to predict the environmental effect of a new headland or structure on a bay beach.

Parabolic Equation for Bay Beaches in Static Equilibrium

Hsu and Evans (1989) developed a parabolic equation to fit the peripheries of 27 cases of bay beaches believed to be in static equilibrium in prototype and model conditions. This equation is more preferred than the log-spiral and hyperbolic-tangent equations for the reasons mentioned above. The equation is reproduced here for further discussion:

$$R/R_0 = C_0 + C_1(\beta/\theta) + C_2(\beta/\theta)^2 \quad (1)$$

There are two independent parameters in Eq. 1. The first is the *reference wave obliquity angle* β , or the angle between the incident wave crest (assumed linear) and the *control line*, joining the upcoast diffraction point to the near straight downcoast beach. The second basic parameter is the *control line* of length R_0 , which is also angled β to the tangent at this downcoast beach end. The radius R to any beach point around the bay periphery is angled at θ from the same wave crest line radiating out from the point of wave diffraction. The three C constants that vary with angle β were generated by regression analysis to fit the peripheries of the 27 data bays used. Examples of bay shape verification can be found in Hsu and

Evans (1989) and Silvester and Hsu (1993, 1997). Flexibility in choosing the downcoast control point is a merit of this empirical approach.

Despite having variable dimensions and indentations between the tip of the headland and the downcoast sandy boundary, the stability of a bay beach can now be determined using this parabolic bay shape equation. Values of the non-dimensional ratios of R/R_0 versus increments of 1° or 2° of β from 20° to 80° can be tabulated. This facilitates potential applications to locate the pairs of (R, θ) manually without the need of a computer, once β and R_0 are determined from maps or aerial photographs. When points of (R, θ) are drawn on the plan of the existing beach, the nearness of the existing bay shape to that predicted for static equilibrium can be compared and the beach stability assessed. If the predicted curve, for a hypothetical static equilibrium, is landward of the existing beach, the bay beach is said to be in dynamic equilibrium, or it may become unstable, for diminishing sediment supply.

Beach Erosion and Conventional Protection Methods

Continuous conflict has taken place between humans and nature over the narrow belt directly landward of the coastline of the world, where human pressure has been extensive. Within the flat ribbons of sand, between the sea and the hinterland, there are numerous problems of coastal flooding and beach erosion.

Causes of Human-Induced Erosion

The phenomenon of coastline changes are often complicated by oceanographic and meteorological effects on the inherent geological factors (form and material). With swell waves, nature helps move sediment landward to build up the berm and dune, while storm waves transport a large quantity of material to form a protective bar, causing beach disappearance. If waves approach a beach obliquely, a longshore current is induced, which promotes longshore sediment transport, or *littoral drift*. Compared with other landforms on the earth, which have evolved over a vast stretch of time and space, changes in high-tide shoreline positions and variations in beach profile may take place in a matter of hours. It is within this relatively rapid timescale in topographical change that has attracted the attention of many geographers and coastal engineers.

Coastline changes may be produced naturally or human-induced. Natural causes to beach erosion may include wave obliquity, storm attack, wind blown sand, existence of natural headlands, imbalance of sediment transport due to various topographical features, and sea-level rise. Although beach erosion has occurred naturally in many places, the problem is more serious due to the activities of people on the narrow

coastal strips locally or elsewhere. Overall, the major causes of human-induced erosion may due to: (1) disturbance to continuity of littoral drift, (2) wave sheltering by coastal structures, (3) offshore movement of sediment, (4) reduction in sediment supply from upcoast, (5) dredging or extraction of sand and gravel for construction, and (6) land subsidence (Uda 1997; Hsu et al. 2000). Among these, human intervention in and interception of sediment supply have been considered two of the most detrimental factors causing beach erosion in many countries around the world. However, some sources of erosion may be originated from a distant place away from the destination – the beach in erosion. For example, damming a river (for flood control, water supply, or power generation) reduces sediment supply to the beach. More recently, breakwater construction for fishing harbors and commercial ports have also caused beach erosion downcoast, with harbor planners and many consulting engineers responsible for the problems they have caused without considering the geomorphic effect on the beach.

Conventional Coastline Protection Methods

The family of seawalls (including bulkheads, revetments, sea dikes, and normal seawalls) were the very first structures ever constructed on a coast for protection against beach erosion and coastal flooding. They are built parallel to the beach at variable locations in relation to the local beach and surf. Their faces fronting the wave action may be vertical or inclined, with or without armor protection. They may even incorporate wave dissipation blocks near and in front of their toes, to reduce wave energy that causes scouring to the bottom at the toe. Beach flanking immediately downcoast of a long seawall is also common, for which some protection is still required.

Later groins were used to intercept littoral drift at places where erosion had occurred. They usually run normal to the beach and may reach out to the limit of the surf zone. Their length and height vary depending on the purpose they meant to serve. This type of structure has been widely used in many countries. Modern groins may be slightly curved, inclined to the local shore, or even in L-, T-, and Y-shaped or fishtailed. A bay beach may form downcoast of a protruding groin or between two units, where the tip of the upcoast unit serves as the point of diffraction, or upcoast control point for the bay beach so formed.

After groins, construction of detached breakwaters has become popular worldwide. They are either single or mostly in groups, with sandy salient or tombolo formed in their lee. In Japan alone, there were 7,371 units of such structures around the country by 1996, totaling 837 km (MOC 1997; Hsu et al. 2000). However, a new trend in Japan has been to replace them with submerged structures or artificial reefs, for aesthetic reasons.

More recently, beach nourishment has become the most “costeffective” alternative for coastal protection and creating recreational beaches, especially in the United States (Bird 1996). Often the beach fills were not protected by suitable structures, so replenishments were required at relatively frequent intervals. It has been envisaged that the cost of maintaining a wide beach would increase due to transporting the material from a distant source. In some cases, beach compartmentation was implemented.

Engineering Applications of Coastal Geomorphology

A trend has recently emerged in applying the principle of coastal geomorphology, especially the concept of stable bay shape, for beach protection. Examples showing a range of other engineering applications can also be found in the literature (Silvester and Hsu 1997).

Stability Verification for Existing Bay Beaches

With the parabolic bay shape equation (Hsu and Evans 1989), it is now possible to verify the stability of an existing sandy bay beach. The general procedure is as follows (refer to Eq. 1, with Figs. 1 and 2):

1. Draw a tangent from a point (referred to as the *downcoast control point*) on the straight downcoast section of a bay beach, and relocate this tangent to the point of wave diffraction (the *upcoast control point*), thus representing the *wave crest line* in the definition sketch (Fig. 2),
2. Denote the *control line*, by joining the upcoast and downcoast control points, assign the distance between them as R_0 ; also measure the reference obliquity angle β ,

3. Calculate the values of radii R for a range of corresponding angle θ (for $\theta \neq \beta$), using Eq. 1 or a prepared table of R/R_0 , so to give sufficient pairs of (R, θ) on the beach,
4. Sketch the predicted bay shape in static equilibrium by joining the points (R, θ) drawn on the existing beach planform,
5. Determine the stability of the existing bay beach by its nearness to the curve given by the prediction.

Should the existing bay shape conform well to the predicted bay shape in static equilibrium, the beach is said to be in *static equilibrium* under the prevailing swell condition. On the other hand, if the existing shape is seaward of the predicted curve, the beach is in dynamic condition, implying either in *dynamic equilibrium*, when sediment balance is maintained, or *unstable*, should sediment supply decrease. However, it must be remembered that the stable high-tide shoreline being predicted applies to swell condition or calm weather. When storm waves arrive, the beach berm will be eroded and material transported offshore to form a submerged bar, which may take some days or longer to return. In the case of static equilibrium, the same high-tide shoreline may result later, but all infrastructures should be kept landward of the receded storm limit.

The stage of bay beach stability may be switched between static and dynamic equilibrium. It can be either from a dynamic to another dynamic condition, or from a dynamic to static, or from static to a dynamic condition, depending on the initial condition of the bay beaches and variability in sediment balance and construction or extension of breakwater (Hsu and Silvester 1996). This concept of interchange ability for beach stability is extremely useful for practical applications. For example, it can be applied to: (1) the environmental impact study upon constructing or extending a jetty or

Engineering Applications of Coastal Geomorphology,
Fig. 2 Definition sketch for a parabolic bay shape in static equilibrium

breakwater within a bay beach in static equilibrium, and (2) the stabilization of a bay beach in eroding condition by locating the tip of a new headland to be installed at a proper location. In these situations, a stable bay beach in static equilibrium is created, thus minimizing the need for protective structures to be constructed downcoast later on.

Any new attempt to construct a jetty or breakwater for a marina or harbor at or within a bay beach already in static equilibrium will result in accretion in the lee at the expense of erosion downcoast, unless certain preventive measures are in place. This natural reshaping will take place within the entire embayment upon the construction of a new headland, despite some modest attempts with seawalls, groins, and detached breakwaters to prevent its fruition. On the other hand, should an engineering task be to construct a breakwater within a bay in dynamic equilibrium; the beach can conveniently be converted into static equilibrium by choosing a proper location for the tip of the new structure. This geomorphic approach of preventing beach erosion should benefit the community as a whole, in addition to the traditional engineering need for providing calm waves within a harbor.

Stabilizing Eroding Beaches

To combat widespread beach erosion, conventional methods have been used as mentioned in the previous section. Instead of constructing hard structures to defend the eroding beaches, it would be better to create a coastal environment in which the beach can protect itself by the formation of bays to meet the condition of diminishing littoral drift. This requires the reorientation of local high-tide shorelines to produce minimal or null littoral drift within the embayment. The concept is termed *headland control*, in which artificial headlands are used to help reorient the high-tide shoreline parallel to the crest lines of the prevailing swell waves. The concept can be applied to stabilize all shapes of eroding high-tide shorelines, be they straight, bayed, or convex in plan (Silvester and Hsu 1993, 1997). The artificial headlands may be either one of the conventional protective structures of groins and detached breakwaters with large spacing, or in combination. This can also be used to help retain beach fill staying longer on a renourished beach.

On a straight coast, a system of groins and/or detached breakwaters at close intervals has been used in many countries around the world. The concept of headland control can be applied to modify the conventional protection scheme already in place by removing some units thus widening the distance between them, or to install new headlands if protection did not exist. However, the most important difference, in the headlands used in the conventional defense and the present *headland control*, is in the distance between two adjacent units and their relative orientation to the coast. For a stable beach to form in the vicinity of these artificial headlands the space between two units must be sufficiently large, often to

several wave lengths, thus allowing a beach so formed to dissipate wave energy naturally under swell wave condition. The new beach should also have sufficient width and volume of material to satisfy the need of a design storm condition. Flexibility in varying the length, shape, distance offshore, and orientation of each unit would help optimize the performance of a stabilization scheme.

For a bay beach suffering erosion, due to reduction in supply upcoast and new breakwater construction for a harbor within an embayment, adding artificial headlands at appropriate locations can create several smaller bay beaches in static condition. The planform of these stable bays in static equilibrium can be sketched after simple calculations using Eq. 1, or aided by a prepared table of R/R_0 .

On an eroding convex coast, such as a barrier beach or spit, its narrow section may be overwashed or breached by storm waves accompanied by storm surge. Most barrier beaches have retreated in the past decades due to the supply from upcoast being drastically reduced. Attention should be given to a geomorphic solution rather than by hard structure alone. A series of stable bay beaches is preferred to a system of groins. The headland control concept allows the units to be installed with variable length, inclination to the coast, distance offshore, and spacing between units. The distance offshore and space between units should be gradually reduced in a cascade manner, thus allowing the local coastal processes to approach natural conditions. The reference wave obliquity angle/used in Eq. 1 for the successive bays formed between headlands should vary, being greater at the farther downcoast, where closer spacing is also desirable.

Salient Planform Behind Single Detached Breakwater

Waves diffract and refract in the lee of a detached breakwater and produce a nearshore current circulation system extending beyond the region of the shadow zone covered by wave diffraction. Consequently, sand accumulation in the form of salient or tombolo may occur behind the breakwater, depending mainly on the material available, the length of breakwater and its distance offshore from the original high-tide shoreline. Hsu and Silvester (1990) have demonstrated that the distance of the salient apex from the breakwater is preferred to that from the original high-tide shoreline, since the former relates more to the wave energy input and the effect of wave diffraction. Previous studies using the latter have resulted in unacceptable scatter when plotting the salient dimension versus the ratio of breakwater length and distance offshore.

They also illustrated that the curved beaches so formed can be related to the bay shape in static equilibrium, for which Eq. 1 can be applied. The analysis is limited to the case of normal wave incidence. The accretion assumes a parabolic form to a theoretical apex whose position can be determined using the dimensionless ratio of offshore distance to the

length of the breakwater, for which a table has been available (Silvester and Hsu 1997). This accretion is at the expense of the material beyond the extremities of the detached breakwater, and hence erosion at beaches downcoast. The final waterline at some distance either side of the breakwater will recede landward, implying beach erosion in this vicinity. However, to the knowledge of this author, this distance between the original high-tide shoreline and the receding one has not been fully quantified whether in laboratory experiments or in field conditions.

In the case of a salient formed in a multiple detached breakwater system, an accurate prediction method is not available. An attempt was made to analyze the planform using the same dimensionless ratios, as for single detached breakwater, and the gap width between units. However, the correlation based on the field data of the salients and tombolos collected in Japan did not yield reliable results for practical applications (Hsu and Silvester 1989).

Stabilizing Beaches Downcoast of Harbors

Many new harbors of variable capacities were constructed on coasts where no natural shelter is available, such as coastal indentation, offshore islands, headlands, capes, barrier spits, or reefs. This requires an initial breakwater to be built and possibly some extension over time as further commercial expansion demanding a large port, hence longer and larger structures. Even until recent time, harbor engineers and planners have considered that the construction of a harbor has priority over coastline evolution downcoast. They have often ignored the principle of geomorphology that would cause beach accretion in the lee of offshore breakwaters and erosion downcoast. Coastal scientists in Greece, Italy, Japan, and the United States have reported adverse effects on downcoast beaches (Silvester and Hsu 1997).

Similar to the sand accumulation behind single detached breakwaters, salient forms in the lee of a harbor breakwater, inevitably cause beach erosion downcoast and a possible silting of the refuge basin at the entrance. Compared with the case of single detached breakwater, a harbor breakwater does not have a clear middle point along its longitudinal axis. With the need for a breakwater to be extended over time due to commercial demand for a larger port, it will produce a larger salient in the lee, and hence erosion further downcoast (Hsu et al. 1993).

Hsu and Silvester (1996, p. 3986) have examined the situation of stabilizing beaches downcoast of harbor extensions. They believe that

In geomorphologic terms, the sandy shoreline of a bay downcoast of a harbor may be stable or in static equilibrium, or could be in dynamic condition, if sediment is still being supplied from upcoast or from downcoast to form a salient predicted by a static bay shape equation. Should commercial expansion demand a larger port, the general solution is to run a breakwater form

the headland or existing structure. This has the potential to create a new static equilibrium beach, often with accretion in the lee at the expense of beach erosion downcoast. It is strongly recommended that geomorphic approach be incorporated to stabilize downcoast beaches early in the planning stage of a harbor, or as remedial measures. By creating bay beaches in static equilibrium, the potential beach erosion downcoast of a harbor will be kept to a minimum or may be prevented completely. (Hsu and Silvester 1996)

Thus, instead of employing the conventional coastal protection method, in which seawalls, groins, and detached breakwaters were used without much success after the erosion downcoast has become serious, bay beaches of variable sizes should be considered to stabilize the eroding beaches. The geomorphic approach, involving the construction of stable bay beaches aided with beach nourishment, can be regarded as a permanent solution for this occasion. With the macroscopic view of the whole coastline rather than looking at a limited section, a better picture of the erosive problem will become clear. As such, erosion can be predicted long before it is likely to take place, and hence means can be devised to prevent it. Case studies have been reported for harbors in Australia, Japan, Taiwan, and South Africa (Hsu and Silvester 1996).

Designing Recreational Beaches

With the economic development around the world there is a community movement demanding a better coastal living environment and full utilization of the coastal zone. As a result, many artificial beaches have been constructed for recreation and tourism, as well as for the restoration of eroding beaches.

Silvester and Hsu (1997) have detailed the requirement for the creation of a stable bay shape for artificial and recreational beaches. One basic requirement is to construct suitable protective structures for preventing sediment loss from the artificial beaches and for providing a calm wave environment. Detached breakwaters with beach nourishment and/or groins have been used in all the cases so far reported in the literature.

Around the mid 1980s, two major Japanese ministries responsible for the preservation and protection of the coast against natural and man-made disasters launched two similar beach protection schemes incorporating hard structures and artificial beaches. These were the coastal community zone (CCZ) projects administered by the Ministry of Construction and the integrated shore protection system (ISPS) under the Ministry of Transport (Hsu et al. 2000).

Most of the beaches so designed are either partially or fully enclosed cells behind offshore breakwaters or between them, hence the term *pocket beaches*. Berenguer and Enriquez (1988, p. 1412) have observed that: "In the recent years, the increase of pocket beaches has been remarkable. In Mediterranean countries where tidal effects are insignificant, especially in Spain, Italy, France, and Israel, this system

of beach regeneration has been widely used because of its rapid results and its economical nature. Japan also has a lot of experience in this kind of work. In Spain, there are over 40 beaches of this kind. They are usually situated on stretches of coastline where there is a lot of tourism and in which there is also a fairly rapid erosional process . . .”.

Coastal Management and Planning

People have used public beaches for various purposes. But, many beaches around the world are still being subjected to erosion, due to improper coastal practices, human greediness and local political pressure for the convenient use on the narrow coastal strips. Coastal protection has also arisen from improper coastal zoning for residential and public development too close to the edge of the ocean, without knowing the stability of the beach involved. Many coastal communities have paid an expensive price through this experience of combating with the recurrent erosion problem. Another example is that landscape architects and consultants, who may not be familiar with the principle of coastal geomorphology, are engaged by an authority to beautify the coastal strips for tourism. Some of the additional facilities so created may fall prey to a storm, so the taxpayer's money is wasted.

It is essential in modern coastal management that beach managers in coastal communities be able to apply the principle of coastal geomorphology, and “to examine such questions as where the beach sediment came from, whether it is still coming, and whether the beach is stable, or shows long-term accretions or erosion, as distinct from short-term cut and fill or seasonal alternations” (Bird 1996).

For any development proposal on a bay beach, the stability of the existing beach should be investigated, prior to giving permission for residential development or structures to be built close to the water. The concept of the stable bay shape of Hsu and Evans (1989) is readily applicable to such cases, without the need of engaging in an expensive and time-consuming exercise, such as physical modeling and computer simulations. If the bay beach is in a dynamic condition, residential development and infrastructures should not be allowed seaward of the predicted static bay limit, plus a little buffer for a storm. Even if the bay is already in static equilibrium, a buffer distance is also required for a storm to act in the future. This would save the need for costly protective measures to be built later. A full investigation may then be carried out only after the preliminary desktop study using the principle of coastal geomorphology, if an elaborate exercise is still warranted.

Geomorphic Engineering: A Future Perspective

Coates (1980) has designated a specific term of *geomorphic engineering* to combine the fields of geology, engineering,

and environmental science together, which used to work independently on coasts. It is also important that biological processes in coastal geomorphology be considered. The traditional single task of coastal protection should gradually be replaced by the preservation of the coastal environment, by creating stable and safe beaches to coexist with nature. It is in such a manner that a careful balance among the conflicting requirements of protection, development, and conservation can be met, with planning and management using coastal geomorphology fulfilling the central role.

Environmental Quality

Michael J. Kennish

Department of Marine and Coastal Sciences, School of Environmental and Biological Sciences, Rutgers University, New Brunswick, NJ, USA

Synonyms

Environmental condition; Environmental health

Definition

Environmental quality is defined in this work as the condition of a particular marine environment (coastline, estuary, bay, harbor, nearshore and offshore waters, open ocean) measured in relation to each of its intended uses. It is usually assessed quantitatively and requires both indices of condition and change and established guidelines and objectives set by environmental health and resource agencies (Harding 1992).

Stressors, Monitoring and Assessment Programs, and Management

Estuarine and coastal marine environments are affected by a wide array of anthropogenic activities that have impacted environmental quality (Kennish et al. 2008; Kennish 2015).

This is so because more than half of the world's human population resides within 100 km of the coast, which creates multiple stressors in the coastal zone (Alongi 1998; Kennish et al. 2008; Kennish 2015). While environmental quality of estuarine and coastal marine environments is most frequently compromised by human activities, that of offshore waters and the open ocean may be adversely affected as well by waste dumping, atmospheric deposition of pollutants, climate change effects, and other human factors.

There are two major categories of anthropogenic stressors on estuarine and marine environments: (1) pollution and (2) habitat and resource degradation. Contaminant inputs from point and nonpoint pollution sources, as well as the physical alteration and destruction of habitat due to dredging and dredged-material disposal, coastal watershed development, marina and harbor construction, marine shipping and transportation, marine mining, mariculture, energy production (oil and gas recovery, electric power generation), shoreline installations, and other human factors, have degraded environmental quality. Overuse or misuse of coastal resources such as overfishing, excessive water withdrawal, subsidence-driven oil and gas extraction, and uncontrolled marine mining not only depletes natural resources but also can adversely affect habitats beyond the limits of sustainability. Overfishing reduces fishery production as well as genetic diversity and ecological resilience (Costanza et al. 1998). Marine sand/gravel mining impacts marine benthic habitats and communities and in some areas can deplete sediment needed for beach replenishment or can exacerbate shore erosion. Poor development planning and inadequate resource management have caused many acute and insidious environmental problems in the coastal zone around the world.

In the USA, enactment of the Clean Water Act in 1972, Clean Water Act Amendments in 1977 and 1987, and Oceans Act in 2000 greatly reduced point source pollution inputs to estuarine and marine environments. Most pollutants now enter these environments from nonpoint sources which are not easily regulated or controlled by land-based technological measures. Similarly, legislation has been adopted in Europe (European Water Framework Directive and European Marine Strategy) that forms the basis for determining the ecological integrity of surface waters of estuarine and coastal marine environments (Borja and Dauer 2008). As noted by Borja and Dauer (2008, p. 331), “An integral part of determining ecological integrity is the measurement of biological integrity, typically emphasizing analyses of plankton, benthos, macroalgae and fish.” They conveyed that effective ecological protection requires the following components: (1) assessing ecological integrity, (2) evaluating if significant ecological degradation has occurred, (3) identifying the spatial extent and location of ecological degradation, and (4) determining causes of unacceptable degradation in order to guide management actions.

Pollution degrades coastal water quality, adversely affects estuarine and marine organisms, causes health risks to humans, and results in diminished human use of coastal environments and resources. Examples include sewage and pathogen inputs, nutrient enrichment and eutrophication, and chemical contaminants (halogenated hydrocarbons, polycyclic aromatic hydrocarbons, metals, and volatile organic compounds). Chemical contaminants in particular can cause behavioral, immunological, neurological, reproductive, digestive, and genetic abnormalities, debilitating diseases, loss of physiological function, and death of estuarine and marine organisms. Pollutants enter estuarine and marine environments from direct pipeline discharges (point sources), nonpoint source runoff, river inflow, atmospheric deposition, and waste dumping. Habitats are impacted by pollutant inputs as well, leading to additional biotic impacts. Chronic exposure of organisms to pollution stress usually results in marked changes in population structure and function, including reduced abundance and biomass, increased mortality, and altered age/size distribution. Recruitment may be significantly reduced. At the community level, responses to insidious and cumulative pollution impacts frequently include dramatic shifts in species composition, decreased species diversity, loss of rare or sensitive species, and dominance by opportunistic species (Howells et al. 1990; Diaz and Rosenberg 1995; Diaz 2015). Imbalances in trophic systems typically occur.

Monitoring is a critical step in assessing environmental quality and determining the necessary management controls to remediate impacts and restore environmental conditions in impaired systems. Assessment of the status and trends in ecosystem health using an integrated approach will yield the information needed for effective long-term environmental management strategies. There are two primary reasons for conducting environmental monitoring: (1) to generate a database to address specific estuarine and marine problems and management needs in a local or regional context and (2) to define the status and trends in environmental quality in a broad spatial context or nationwide (Hameedi 1997). Several elements should be incorporated into estuarine and marine environmental quality monitoring programs to assess ecosystem health: (1) analysis of the main processes and structural characteristics of the ecosystem, (2) identification of the known or potential stressors, (3) development of hypotheses about how these stressor may affect the ecosystem, and (4) identification and application of the measures of environmental quality and ecosystem health to test the hypothesis (Harding 1992).

Meaningful biological measures of pollutant exposure, pollutant-induced adverse biological effects, and susceptibility of biota to environmental degradation are important in environmental quality monitoring programs. Habitat condition should also be targeted. Environmental quality monitoring programs typically include the following: (1) assessment of the temporal trends in the levels of environmental

degradation due to chemical contaminants and other anthropogenic sources; (2) determination of the magnitude and spatial extent of environmental degradation due to chemical contaminants and other anthropogenic sources; (3) incidence of pathological conditions, physiological dysfunction, and biological abnormalities in sentinel organisms resulting from environmental degradation; and (4) formulation of composite indices or sets of indicators that communicate information about the condition of the natural environment and are tractable toward public policy objectives (Hameedi 1997).

In the USA and other developed nations, a focus of estuarine and marine monitoring is the identification of specific sources of stress (e.g., municipal and industrial discharges, groundwater, oil spills, atmospheric deposition, etc.), biotic exposure to pollutants (in the water column or bottom sediments), and pollution effects (on populations, communities, and ecosystems). Biological measures have been used by major marine environmental quality monitoring programs to assess coastal environmental conditions on local, regional, and national levels. In addition, integrated measures of coastal ecosystem health have been applied that aggregate water quality and biological measurements into a quantifiable framework. Examples include the Index of Biotic Integrity, Benthic Index, and Sediment Quality Triad.

It is imperative for marine and coastal policy and management programs to formulate strategies that mitigate pollution inputs and habitat loss. Most effectively, this involves a concerted effort on the part of government agencies (federal, state, and municipal), academic institutions, business and industry, stakeholders, and the general public to address the myriad of problems in the coastal zone and the measures that must be implemented to restore, protect, and maintain the integrity and health of coastal environments. Over the past few decades, great effort has been expended to develop partnerships among these entities to address and resolve environmental quality problems.

An integrated global approach to maintain marine environmental quality has not been effectively formulated. A comprehensive global marine environmental management framework is needed to protect and preserve the integrity of marine systems worldwide. Instead, the global strategies for protecting marine environments derive from a patchwork of international and regional conventions, protocols, agreements, national laws, regulations, and guidelines. Greater international cooperation is needed to more effectively address marine environmental quality problems worldwide.

Conclusions

A consensus-building process has proven to be useful in establishing effective pollution abatement and control programs, revitalizing damaged habitats, managing exploited resources, and restoring environmental quality of estuarine

and marine ecosystems. An approach that has gained favor over the past few decades is to forge partnerships between government agencies, academic institutions, business and industry, and the general public to seek a unified goal for restoring, protecting, and maintaining the health of damaged estuarine and coastal marine ecosystems. Education and outreach initiatives have been implemented to increase public awareness and understanding of pollution and habitat problems, as well as other anthropogenic impacts, and to encourage public participation in the decision-making processes and stewardship of coastal resources. Future environmental management programs must focus on more integrated and well-coordinated initiatives to replace the historically narrow conservation and protection strategies, wasteful land-use practices, unsustainable coastal development (particularly in the face of climate change effects), resource-use conflicts, and escalating habitat degradation in the coastal zone.

Eolian Processes

Patrick A. Hesp

Department of Geography and Anthropology,
Louisiana State University, Baton Rouge, LA, USA

Eolian processes are those processes relating to, or caused by the wind. The term eolian comes from the Greek *Aeolus*, the God of Wind. Eolian (aeolian – non-US equivalent) processes include the transportation and movement of sediments (particularly sand, clay, and silt), erosion of sediments, rocks and landforms, and the creation of dunes, sheets, and landforms. Eolian processes are most common on coasts and in arid environments, particularly hot and cold deserts.

Eolian sand transport is initiated when the wind velocity exceeds a critical threshold velocity. The threshold velocity required to initiate clay and silt transport is far greater than that of sand due to their platy nature and cohesive forces, but once motion is initiated, fine grained material (particularly silt) may stay in suspension for a considerable time period. Three main forms of grain transport take place, creep, saltation, and suspension. Creep refers to the movement of grains by rolling over the surface. Saltation (from the Latin *saltare*, to jump) is the bounding movement of grains in which grains rise almost vertically and then describe a long low trajectory downwind. Once saltation occurs, some energy is transferred to the surface by grain collisions and this aids creep and the ejection of further grains into the air stream. This process occurs at lower threshold velocities than that required for initiation of sediment transport and has been termed reptation by some authors (e.g., Lancaster 1995). Suspension occurs where grains are lifted sufficiently to overcome gravity for some period of time. The initiation of eolian sediment transport and eolian processes are affected by surface conditions (e.g., moisture, cements, and bonding agents, vegetation) surface roughness and topography.

Eolian transport causes deflation, which may merely lead to the slight lowering of a surface (e.g., beach, dune or sand plain), but may also be the dominant process leading to the development of deflation hollows (and slacks), basins, and plains. In coastal and desert environments, deflation leads to the formation of blowouts, parabolic dunes, and wind-eroded plains. Here, deflation erodes the surface down to the seasonally lowest water table, a calcrete or indurated horizon, a palaeosol, or rock and boulder strewn surface. Eolian transport also causes abrasion of landforms. Wind transported sand grains abrade surfaces forming ventifacts (a polished, faceted and/or abraded stone or pebble), yardangs (sharp crested linear ridge of wind-eroded rock), and zeugen (desert rock pillars and yardangs, which are considerably undercut; Whittow 1984).

In the coastal environment, eolian processes may lead to the development of various dune types. Where vegetation is important or present, coppice dunes, shadow dunes, fore-dunes, blowouts, and parabolic dunes may be formed. Where vegetation is less important and sediment supply is moderate to high, transgressive dunefields may occur and display a variety of dune types (e.g., sheets, barchans, transverse and oblique dunes, dome dunes, and star dunes) and associated landforms such as precipitation ridges and deflation plains and basins may be present (Hesp 1999). Deserts may display a wide variety of eolian dune forms including dome dunes, barchans, transverse dunes, longitudinal and linear dunes, shadow dunes, sheets, and star dunes. Each tends to be related to sediment volume, wind directional variability, and average annual velocity (Cooke et al. 1993). Vegetation processes are important in modifying eolian processes commonly leading to the complete colonization of once active dunefields in both coastal and desert environments.

Eolianite

Eric Bird

University of Melbourne, Melbourne, VIC, Australia

Definition

Eolianite, also known as aeolianite, (a)eolian calcarenite, calcareous (a)eolianite, dune limestone, dune sandstone, kurkar (Middle East), or kunkar (India), is a generally consolidated coastal rock formation consisting of at least partially lithified windblown sand. Strictly eolianite could include any windblown sediment, such as silt (loess, brick earth), clay (parna), and volcanic ash, but conventionally it is restricted to dune sand, although finer sediment is sometimes present.

Evolution of Eolianite

Typically, eolianite is dune sand that has been partially cemented by secondary internal precipitation of carbonates from percolating groundwater. There is often evidence of several stages of such cementation. The proportions of carbonate vary but are typically at least 50% and often more than 90%, derived from shell debris, coralline material, bryozoans, and foraminifera, which lived on the seafloor. There are varying proportions of noncalcareous sediment, mainly quartz (quartzose sandstones with less than 50% carbonate are termed quartz-arenites).

Eolianite was originally described from Bermuda by Sayles (1931), although it had been noted by explorers on the Australian coast, where Vancouver in 1791 thought it was coralline while Charles Darwin in 1844 reported that it consisted of windblown sand and associated limestone. It is usually of Pleistocene age and may be overlain by unconsolidated Holocene dune topography. It often passes well below present sea level, for example, the eolianites of the Nepean Peninsula in Victoria, Australia, are Pleistocene dune formations, which extend more than 140 m below, and up to 60 m above, present sea level (Bird 1993). They contain fossil shells, plant remains, and occasional evidence of land animals.

Eolianite dune formations have been emplaced on the coast during Quaternary oscillations of land and sea level. During falling and low sea-level phases, sand derived from calcareous seafloor organisms was winnowed and carried landward by onshore winds to be deposited as transgressive dunes in the vicinity of the present coast. Similar sand was also carried shoreward during marine transgressions to form beaches and backshore dunes, as well as multiple beach and dune ridges parallel to the coastline. In southeast South

Australia, a series of eolianite ridges mark successively uplifted coastlines inland from, and parallel to, the present coastline between Cape Jaffa and Discovery Bay. They are separated by swampy swales that were formerly coastal lagoons like the Coorong, which extends behind the calcareous sand barrier on the coast of Encounter Bay.

Many eolianite coasts have a series of partly overlapping transgressive dune formations, indicating alternations of surface stability, when a capping of soil and vegetation developed, and instability, when the next transgressive dune moved in (Fig. 1). Each dune formation is capped by a soil horizon (paleosol) overlying a calcrete (limestone) layer formed by subsoil precipitation of carbonates. Traced laterally, these soil and calcrete layers vary in thickness and rise and fall as they mark out the contours of successively formed dune landscapes. Contemporary vegetation produced calcareous fossil root structures (rhizoconcretions) in the subsoil. The interbedded soils are up to 3 meters thick, typically terra rossa, incorporating eolian silt and clay accessions to the dune surface. Occasionally, the footprints of animals or birds are found on outcrops of sandstone, which were temporary land surfaces, buried when dune accretion resumed. Locally, there are soil pipes, cylindrical hollows formed where root penetration was followed by the local subsidence of soil into depressions deepened by solution and encased by precipitated calcrete. In places there are unconformities because the earlier dune landscape was eroded before the next dunes arrived. Gravel layers formed by the disintegration of calcrete outcrops during such erosion phases occur locally, sometimes cemented as breccias. Each phase of landscape stability came to an end with the arrival of the next transgressive dune formation, marked by dune sandstone, often with laminations (dune bedding) indicating the intermittent advance of a dune front and sometimes with calcareous fossil

stem structures (phytoconcretions) formed around buried vegetation. Subsequent erosion may expose root and stem concretions as “petrified forests,” as at Cape Bridgewater, Australia, and on Lord Howe Island, the dune calcarenite cliff behind Middle Beach shows columnar structures that were the trunks of palm trees engulfed by a rapid dune advance, the wood having been subsequently replaced by precipitated carbonates.

Commonly eolianites are capped by Holocene dunes, but where these are absent (or have been removed by erosion), exposed calcrete layers can develop karst topography (limestone mounds or ridges, pedestals, clay-floored vases and ditches, solution hollows). Some dune sandstone formations remain relatively unconsolidated and can be mobilized by wind action as active dunes if the overlying calcrete crust is removed.

Eolianite dune formations are sometimes sufficiently lithified to be cut back as cliffs up to 60 m high, the harder components (calcrete layers) dominating the profile while caves and coves are excavated in the less consolidated dune sandstones. These cliffs are fronted by subhorizontal low-tide shore platforms formed where shore rock outcrops are lowered by solution processes to a level that has become indurated by further carbonate precipitation (Hills 1971) (Fig. 1).

Eolianite dune topography is found on the southern and eastern coasts of the Mediterranean, in Morocco, on the Red Sea and southern Arabian coast, in western India, around the Caribbean (Kaye 1959), on the Brazilian coast, in South Africa, on oceanic islands such as Mauritius and Hawaii, and extensively along the western and southern coasts of Australia (Fairbridge and Teichert 1953; Semeniuk and Johnson 1985). On the eastern coast of Australia, beaches and dunes are quartzose, and eolianites have not formed: the

Eolianite, Fig. 1 Cliff and shore platform cut in eolianite at Jubilee Point on the coast of Victoria. The cliff section shows two Pleistocene dune calcarenite formations capped by calcretes and paleosols (arrowed), surmounted by unconsolidated Holocene dunes. The subhorizontal shore platform is exposed at low tide (Copyright-Geostudies)

dunes remain unconsolidated, either active and mobile or retained by a vegetation cover. On the eastern coast of the Mediterranean, there is a similar transition, the eolianite (kurkar) dune topography of the Israel coast passing southward into more irregular, mobile dunes on the coast of the Gaza Strip, where the sands have an increasing proportion of terrigenous (Nile-derived) quartzose sediment.

The submergence and dissection of eolianite dune topography formed during low sea-level phases are illustrated off the western and southern coasts of Australia. The rising sea during the Holocene marine transgression breached eolianite ridges and isolated Rottnest Island and Garden Island in Western Australia, submerging Cockburn Sound. Some submerged eolianite ridges have been planed off by wave action on the seafloor, but there are also remnants of submerged eolianite dune topography. Similar submerged eolianite dune ridges occur off the Bahamas, northeast Brazil, and Sri Lanka, and some of these have become reefs with coral and algal crusts.

Summary

Eolianite is a generally consolidated coastal rock formation consisting of at least partially lithified windblown sand. It occurs as dune formations that have been emplaced on the coast during Quaternary oscillations of land and sea level and contain calcareous sediment derived from biogenic deposits on the seafloor. Parallel or overlapping dune formations have been lithified by precipitation of carbonates and include calccrete layers and paleosols.

Some have been sufficiently lithified to form coastal cliffs and shore platforms and to be exposed as karst topography.

Erosion of Coastal Systems

Luciana S. Esteves

Department of Life and Environmental Sciences, Faculty of Science and Technology, Bournemouth University, Poole, UK

Definitions

Coasts can be defined and better understood if they are analyzed as systems. Systems are composed of identifiable entities (elements or subsystems, such as cliff, dune, beach, nearshore), which change attributes (size, shape, elevation) and interact (changes in one will affect the other) in response to varying inputs of energy or matter. Generally, coasts are open systems (inputs can be gained or lost by the system) in a state of dynamic equilibrium, i.e., changes in morphology occur as the system adjusts to the varying inputs. The temporal and spatial scale in which the coastal system should be defined will depend on the issues or questions that are being analyzed (Woodroffe 2003). Analyzing coasts using a “systems theory” framework can help elucidating the complex nonlinear interactions that result in coastal change.

Coastal erosion is a morphological change due to loss of material from a coastal system or subsystem. It is generally expressed in terms of reduction in volume, lowering elevation, or landward displacement of a feature of interest, such as the cliff edge, dune toe, or high water line. Coastal changes can be quantified using net values or rates of change. Coastal systems are dynamic, and the rate and direction of change can vary through time; therefore, it is good practice to indicate the period of time in which changes were measured.

The Coastal System

In a coastal system (Fig. 1), local and regional settings, such as geology, sea-level changes, and sediment availability, are long-term control factors influencing the formation of landforms at varying spatial scales. The geology influences the configuration of coastlines (e.g., the presence of headlands and cliffs) and whether a local sediment source may be available (e.g., debris from chalk cliffs tend to dissolve rather

than form sand or silt particles). Geology can also control the rate of change and their variation through time and space. For example, cliff retreat is generally slower in sections exposing hard rocks or more resistant sedimentary rocks than in sections of poorly consolidated sedimentary strata. In coastlines formed by folded rocks, erosion rates can vary depending on whether the different angles of dip can increase or decrease the susceptibility to erosion.

There are fundamental differences in the temporal variability of coastal changes between cliffed and low-lying sedimentary coasts. Cliffed coasts are erosional in nature, and cliff retreat is irreversible (i.e., there is no natural recovery from a cliff top retreat). Additionally, changes in cliffed coasts tend to be episodic, with large changes occurring in short periods of time interspersed with longer periods of very little change. In contrast, beaches show periods of accretion and

erosion as the morphology adjusts to decreasing and increasing wave energy, respectively. In low-lying sedimentary coastlines, both average and extreme forcing conditions are important drivers of coastal morphodynamics, and fluctuations in shoreline positions are more sensitive to sediment availability.

The iconic Durdle Door (Fig. 2), in the World Heritage Jurassic Coast (Dorset, southwest England), is an arch formed by wave erosion in an almost vertical limestone. This limestone is more resistant to erosion than the soft chalk cliffs and other sedimentary formations that are presently seen landwards. The tectonic movements that formed the European Alps caused intense folding of the rocks forming this coast and hence the vertical limestone. The spatial variation in the position of the shoreline (and rate of erosion) is influenced by the complex geology and fluctuations in water levels, which

Erosion of Coastal Systems,

Fig. 1 Schematic representation of a coastal system showing its components (landforms, sediment dynamics, biota, and, increasingly more important, human interferences), long-term control settings (geology, sea level, and sediment availability), and forcing conditions

Erosion of Coastal Systems,

Fig. 2 Section of the Jurassic Coast in Dorset (southwest England), where the position of the shoreline is influenced by the geology, with the chalk cliffs eroding faster than the limestone

control how often waves reach the cliff base. This eroding sedimentary coastline is prone to landslides, and cliff retreat is highly dependent on their frequency. Data from the British Geologic Survey landslide database show that the number of landslides increases after prolonged periods of heavy rainfall, particularly in southwest England (Pennington et al. 2015), where the Jurassic Coast is located. Although chalk does not supply beach-forming material, these cliffs have bands of flint nodules, which form the gravel found at the local beaches.

As a conditioning long-term factor, sediment availability is determined by a combination of geology, sea-level fluctuations (i.e., changes in physical accommodation), and exchanges in and out of the system, which in shorter-time scales vary as a function of forcing conditions. Most commonly, forcing conditions include a combination of wind, waves, tides, and currents, with their relative importance varying geographically. Coastal systems can be wave-dominated, tidal-dominated, river-dominated, or of mixed-energy depending on the type of process having the greater influence on sediment dynamics and landforms (Boyd et al. 1992).

Within a coastal system, erosion and deposition can occur concomitantly and vary spatially, in such a way that some subsystems may erode while others accrete. The system responds to changes in forcing conditions through morphodynamic adjustments (Wright and Thom 1977). The morphodynamic state of a coastal system is determined by the interactions taking place within the coastal system (how changes in one subsystem influence another) and the changes driven by external forcing conditions. The time that a system takes to reach equilibrium with the new conditions is called the relaxation time. Most studies are focused on explaining or quantifying erosion of particular subsystems (e.g., dunes or beaches) or within specific areas of a coastal system. Studies that are very detailed on a particular subsystem are called reductionist (Woodroffe 2003). Reductionist studies may identify and quantify beach erosion in a particular subsystem, while accretion or deposition in other subsystems may go undetected.

Landforms are shaped by a combination of (a) forcing conditions and the interactions they drive within the coastal system (i.e., the resulting hydrodynamics and sediment dynamics), (b) the presence of biota (i.e., the presence of vegetation or organisms that can change the susceptibility to erosion, transport, or deposition), and (c) human interference, which is increasingly pervasive affecting coastal systems' entities, attributes, and interactions both directly and indirectly (Fig. 1). In some situations and depending on the scale in which a coastal system is analyzed, it can be argued that human interference is also altering forcing conditions, therefore, playing a major role in determining the characteristics of the system. For example, tidal barrages can control tidal levels altering the tidal prism, current velocities, and duration of wet and dry conditions. Construction of dams

(sometimes many kilometers from the coast) can reduce the amount of sediment arriving at the coast, resulting in a sediment deficit that creates or exacerbates coastal erosion.

The Role of Feedback

Interactions between subsystems often relate to feedback mechanisms that are important to determine the dynamic state of a coastal system. These feedback mechanisms are evidences of the nonlinear and complex relationships characterizing coastal dynamics (Woodroffe 2003). Most commonly, interactions are self-regulating through negative feedback, i.e., the resulting morphological change will counteract its driving conditions inhibiting further changes. Negative feedbacks tend to maintain the coastal system in a state of equilibrium. A typical example of a negative feedback is the formation of nearshore bars as a result of beach erosion due to storm impact. The nearshore bar will cause waves to break, reducing the wave energy reaching the beach and, consequently, preventing further erosion. After the storm, as lower wave energy conditions return, the nearshore bar migrates landward and welds to the beach restoring sediment levels.

Positive feedbacks promote the continuation of change until a threshold triggering a different response is exceeded. An example of positive feedback is the formation of dune blowouts (Woodroffe 2003). Once the dune vegetation is removed in a certain area, it increases the exposure of sand to transport by wind, which will affect adjacent vegetation due to loss of substrate and damage by increased winds and/or smothering by mobile sand. Therefore, after the initial disturbance, blowout growth will continue due to vegetation degradation and increased exposure to aeolian transport. Positive and negative feedbacks have a key role in self-organization as a mechanism for changes in coastal morphology, as suggested for the formation of beach cusps. According to Coco et al. (2003), cusps' horns and bays develop through a positive feedback between the morphology and swash flow, which enhance the cusp relief up to a point when there is a decrease in differential erosion and negative feedback stabilizes the morphology.

Scales of Coastal Change

Erosion often occurs as part of natural cycles (working at a range of temporal scales) characterized by changing energy conditions that result in alternating periods of erosion and accretion. In most cases, erosion could be perceived as a temporary state, the erosional phase of a cycle, some of which lasting thousands of years, such as glacial and interglacial periods, while others may last few months, such as seasonal weather patterns determining the frequency and intensity of storms (Table 1). Considering the geologic (very long) time scale, dynamic processes with influence at the

coast tend to smooth out its configuration, as headlands are eroded (concentration of energy) and the sediment available is transported toward coastal embayments where it is deposited (dissipation of energy). It is due to tectonic uplifts, isostatic rebounds, and sea-level changes that coasts continue to be rejuvenated and have the diverse and remarkable landscapes that are so widely appreciated.

In this context, erosion is a natural process and of great importance for the dynamic equilibrium of coastal systems. It reflects the natural capacity of coastal systems to make morphological adjustments in response to changes in forcing conditions (i.e., energy and/or sediment inputs). However, in many locations, human activities have altered the natural environment, affecting the biota, coastal landforms, sediment dynamics, and their interactions (Fig. 1), in ways that have hampered the natural adaptive capacity of coastal systems. Most often, human interferences drive positive feedbacks that enhance change and push the system to exceed thresholds that can alter trends and response mechanisms. For example, revetments can reduce cliff retreat but create or aggravate sediment deficit, as cliff erosion will no longer supply material to the beach system. Additionally, wave reflection caused by the revetment can increase erosion resulting in lowering beach levels. In most cases, a reduction in sediment supply combined with an enhancement of sediment removal will increase the relaxation time or cause a shift in the system.

In the literature, scales of coastal changes have been described using a variety of terms that are not necessarily standardized or applied consistently (cf. Cowell and Thom 1994; Stive et al. 2002). Decadal changes may be considered as “short term” in a study of coastal evolution associated with sea-level fluctuations in the Quaternary and as “long term” in research assessing seasonal or interannual changes due to the impact of storms. Table 1 shows the terminology used to reflect the different temporal scales and examples of natural processes as suggested in Stive et al. (2002). Their original

table includes spatial scales, which are omitted here to avoid misinterpretation. Although it is possible to suggest the potential spatial scale in which the different natural processes may have an impact, the actual extent of such influence in any specific location will depend on the interactions with other processes acting at different scales and the characteristics of the coastal system.

Due to the widespread impact of human-induced processes on coastal changes, examples are included in Table 1. Contrasting with natural processes, which are commonly related to cycles, human-induced coastal change is most often episodic but causing long-lasting impacts on coastal systems. Human-induced impacts can alter the dynamics of coastal systems favoring erosion, transport, or deposition at levels that may take a considerable time for the system to recover or reach dynamic equilibrium under the new conditions. Therefore, in Table 1, the temporal scale associated with the human-induced processes should be interpreted as the likely duration of the impact or the time in which the system may reach dynamic equilibrium after disturbance (the relaxation time).

Causes of Coastal Erosion

There are several causes or factors acting at a range of temporal scales (Table 1) that can contribute to coastal erosion. Evidence of coastal erosion can be easily identified worldwide (Fig. 3) in the form of beach or dune scarp, cliff failure, fallen vegetation, and exhumation of relict deposits, just to mention a few examples. In very general terms, erosion will result from a reduction in sediment supply caused by (a) changes in forcing conditions (usually an increase in energy conditions and/or decrease in sediment input) or (b) natural or human-induced alterations within the coastal system that will result in shifts in the sediment dynamics (e.g.,

Erosion of Coastal Systems, Table 1 Temporal scales of coastal changes associated with natural (Adapted from Stive et al. 2002) and human-induced processes or factors (arrows indicate factors occurring across scales)

Scale	Temporal scale	Natural processes or factors	Human-induced processes or factors
Very long term	Centuries to millennia	Geological setting Long-term climate change ↑ Relative sea-level change Sediment availability	Anthropogenic climate change
Long term	Decades to centuries	↓ Regional climate variations Coastal inlet cycles ↑ Migration of sand waves Extreme events	Sediment retention by dams Stabilization of inlets ↑ Obstruction of littoral drift by hard engineering structures
Middle term	Years to decades	↓ Wave climate variations Surf zone bar cycles	↓ Degradation of coastal wetlands Land reclamation Removal of dunes
Short term	Hours to years	Seasonal weather patterns Oceanographic conditions	Managed realignment Beach nourishment

Erosion of Coastal Systems, Fig. 3 Some examples of coastal erosion evidence: (a) beach scarp in Oceanside Beach, (California, USA); (b) vegetation holding a backbeach scarp in Cayo Guillermo (Cuba); (c) gravel washover fans in Medmerry (south England) stripped sediment from beach exposing relict deposits; (d) erosion of soft cliffs in Arboletes (Antioquia, Colombia) where some families had to be relocated further inland; (e) dune scarp in Hermenegildo (southern

Brazil); (f) aeolian transport in an incipient blowout in the Sefton coast, one of the fastest eroding shores in the UK (Formby, northwest England); (g) exhumation of peat and lagoonal muds where the Conceição lighthouse collapse due to beach erosion in 1995 (southern Brazil); (h) a lighthouse close to the edge of a retreating cliff in Richards Bay (KwaZulu-Natal, South Africa); (i) rock platform along the Coogee to Bondi walk (Sydney, Australia)

loss of vegetation able to promote sediment stabilization). The most commonly cited causes of erosion include storms (mainly due to increased wave energy and water levels), relative sea-level rise, coastal engineering works, and other interferences related to human occupation. In most locations, erosion will result from a combination of these factors. The relative importance of each factor varies geographically and depends on the time scale of analysis. Tsunamis and other extreme or rare events not mentioned above may be important at specific locations.

Storms

Storms are events of high wave energy driven by strong winds, sometimes leading to storm surges and increased longshore sediment transport (when waves approach the coast at an angle). In storms, waves are higher (have more energy) and break across a wider surf zone, where they are able to put sediment into suspension. Once in suspension, particles are more easily transported by currents both cross-shore and alongshore. Higher waves result in the movement of larger particles and stronger longshore currents (the speed

will also depend on the angle of wave approach), which in turn can increase the volume of sediment being transported. Therefore, high-energy waves are the key factors enabling coastal erosion during storms. Considerable erosion can result from the impact of individual large storms, a cluster of storms, or a storm season (usually but not always the autumn or winter).

Not all coasts show the same susceptibility to storm impact. Rocky coasts will be less affected than sedimentary coasts, and these tend to be more resilient in areas where high-energy conditions are more common than in areas where stormy conditions are less frequent (Cooper et al. 2004). The magnitude of impact will depend on (a) the characteristics of the coast, including sediment type and availability, (b) whether the dynamic processes at hand are able to exceed the thresholds required for erosion to take place, (c) duration of the storm or stormy period, and (d) storm frequency (as this will determine whether there is time for recovery between storms). In low-lying coasts formed by unconsolidated sediment, this threshold is defined by the critical bed shear stress and particle size. Retreat of soft cliffs may occur when the cliff face is destabilized by removal of sediment at the cliff base (exceeding the angle of repose) or by overload due to water saturation (usually triggered by rainfall combined with wave action at the cliff base).

In coastal areas, strong winds can cause widespread and critical damage to infrastructure, sometimes causing fatalities associated with falling trees, broken electric cables, or flying debris. However, erosion due to aeolian transport may be restricted under certain conditions. Winds can be a direct cause of erosion of non-cohesive sediment (mainly sand) when surfaces are dry and vegetation is absent. Rainfall is an element of most storms, and higher water levels tend to “wet” a wider part of low-lying coasts, which precludes wind transport. However, winds play a key role in increasing wave heights and contributing to storm surges.

Storm surges are temporary high water levels exceeding the predicted astronomic tidal level due to a combination of wind setup (i.e., strong onshore winds force water toward the coast increasing water levels), wave setup, and lower atmospheric pressure. In general terms, the water level increases 1 cm for each one millibar drop in atmospheric pressure. In hurricanes, for example, the atmospheric pressure in the eye of the storm is considerably lower than outside the storm. Besides influencing water levels, this gradient determines the wind speeds. Atmospheric pressure as low as 909 millibars was recorded at the eye of hurricane Maria before the landfall in the Caribbean islands of Dominica as category 4 and Puerto Rico as category 5 (on 18 and 20 September 2017, respectively). Considering that the average atmospheric pressure at sea level is around 1013 millibars, a drop to 909 millibars would account for an increase of 104 cm in local water levels.

At landfall in Puerto Rico, the storm surge reached 180 cm, and sustained wind speeds were 155 mph.

The main contribution of storm surges to coastal erosion is that the higher water levels allow waves (and associated currents) to reach areas that are not usually exposed to them. Therefore, waves will affect a larger area, including zones that may be less resilient to change and more prone to erosion. Dune scarping (Fig. 3e) can occur when high water levels enable wave erosion at the dune toe. In mesotidal or macrotidal locations, storm surges will have a greater impact if occurring around high tide; as at other times, it will only reach areas already within the tidal range. In urban areas, storm surges are a great flooding hazard due to overtopping of seawalls. Similarly, storm surges can facilitate beach erosion due to overwash, which occurs when water levels are high enough to transport sediment from the beach over the dunes or coastal ridges and deposited behind them as washover fans (Fig. 3c). Beach erosion through overwash contributes to coastal retreat and barrier rollover (typically triggered by rising sea levels).

Storm impacts on beaches are often described in terms of changes in beach profile, which can result from individual storms or from seasonal changes in wave energy. Profile changes are a result of cross-shore transport, in which high wave conditions move material from the beach to the near-shore. If water levels are high, waves can erode the dune toe or base of the cliff and supply material to the beach, as was observed in Thorpeness (Suffolk, east England) after the cliff base retreated around 5–6 m after a storm in June 2010 (Fig. 4). A similar change was observed after a prolonged stormy period during the 2013–2014 winter. It is important to note that the tidal range in Thorpeness is just over 2 m and the effect of storms on cliff retreat requires a storm surge to coincide with high tide.

Most often, storms are likely to erode material from the beach, lowering beach levels and supplying sediment to raise the seabed in the surf zone. The beach profile tends to become steeper than its pre-storm conditions and assume a concave shape. One or more nearshore bars can form, which, combined with the accreted seabed, will help dissipate wave energy and prevent further erosion. After the storm, constructive waves bring the sand back to the beach. When sediment deficit develops due to loss of material that was transported either cross-shore or longshore, the beach may take longer to recover after a storm or may not fully recover.

Climate Change and Relative Sea-Level Rise

Enhanced erosion and flooding of low-lying coasts are the most often cited impacts of climate change on coastal areas, which are expected to occur as a result of sea-level rise and enhanced storminess (e.g., FitzGerald et al. 2008). Due to increasing global average temperatures since the Last Glacial Maximum, sea levels have been rising 100–120 m in the last

Erosion of Coastal Systems, Fig. 4 Beach profiles measured just north of the Thorpeness village (Suffolk, east England), approximately at the location where they are overlain (photograph

date: 22 Apr 2017). Note that the first and last profiles were measured in the winter, all others in the summer. (Data provided by the Environment Agency)

20,000 years or so. Although there is much debate on the magnitudes and rates of change (e.g., Horton et al. 2014), there is little doubt in the scientific community that the global trend of sea-level rise exists and will continue throughout the twenty-first century. However, it is important to recognize that estimates of global averages might not be relevant at the local level, as the rate of sea-level change at any particular location is influenced by a range of local and regional factors (e.g., Woodroffe and Murray-Wallace 2012).

There is less certainty about the predictions of increasing frequency and intensity of storms due to inconclusive results from both models and analyses of historical data (e.g., Esteves et al. 2011). The uncertainty in the results of these studies is mainly related to constraints of data availability (e.g., times series of data are relatively short and restricted to few locations) and the high variability in meteorological and oceanographic conditions inherent to seasonal, interannual, and decadal cycles. Therefore, it is possible that the signal of enhanced storminess cannot yet be identified, but the likelihood of it happening should not be ignored. An increase in the frequency and intensity of storms could lead to greater mobilization of sediment, resulting in faster and/or more widespread coastal retreat. However, erosion can also release sediment to the coastal system, and this could either reduce erosion or promote accretion in some areas.

Sea-level rise driven by climate change occurs as a result of an increase in water volume in the world's oceans due to both thermal expansion of seawater and the melting of glaciers and ice sheets. At long and very-long temporal scales, sea-level fluctuations are a key factor determining the configuration of coastlines over hundreds of kilometers. For example, the ubiquitous presence of barrier islands along the east coast of the USA is a result from over 100 m rise in sea level in the last 20,000 years (since the Last Glacial Maximum). The melting of land-based ice during interglacial periods (i.e., periods of increasing temperatures) increases the volume of water in the oceans basins. Although this process has worldwide consequences, the effects will vary geographically.

For some time now and partly due to dissemination in the Intergovernmental Panel on Climate Change (IPCC) reports, there has been some emphasis on rates of sea-level rise based on global averages of data collected during the twentieth and twenty-first centuries. The widespread attention on estimates of global averages and associated future predictions contributes to a generalized misunderstanding about their relevance and applicability at the local level without consideration of spatial variations, including for planning purposes (Woodroffe and Murray-Wallace 2012). Although it may be fair to assume that rising sea levels will increase risk of coastal flooding and erosion, the actual coastal response at any site

will depend on a combination of factors with local or regional influence.

The magnitudes and rates of sea-level changes at any specific location usually refer to relative sea level, which is the net difference in sea level considering vertical changes in both the sea surface and land elevation (e.g., tectonics, isostasy, subsidence due to compaction). For example, the melting of ice sheets since the Last Glacial Maximum resulted in isostatic rebound (due to changes in the load of land-based ice) and hydro-isostatic changes (due to the load of the water released from the ice sheet), which still affect the relative sea level in Britain causing regional differences. Isostatic rebound is causing land uplift of more than 1 mm a^{-1} in southeast Scotland and land subsidence of over 1 mm a^{-1} in southwest England (Woodworth et al. 2009). In some locations, uplift due to tectonics or isostatic rebound may balance out or reduce rates of sea-level rise, but other factors can influence the relative sea level, such as the changes in gravitational pull of ice sheets and glacier on adjacent waters (Hsu and Velicogna 2017).

Rising sea levels usually lead to shoreline retreat due to marine transgression (i.e., landward displacement of the shoreline) and associated coastal flooding and erosion. If sediment dynamics could be ignored, the horizontal distance of shoreline retreat could be calculated by knowing the change in water-level elevation and the average slope of the coastline. For example, if the slope is about 1.9° , it has a gradient of 1:30 (i.e., one meter change in elevation every 30 m in horizontal distance). Therefore, 1 m rise in sea level would move the shoreline 30 m inland of its current position. However, this is an oversimplification as it disregards any changes in morphology and sediment movement associated with sea-level fluctuations. The actual shoreline displacement will depend on the rate of sea-level change, the availability of sediment, and the morphological changes that will take place.

Marine transgression occurs when the sea-level rise outpaces the accumulation of sediment, increasing accommodation space. Transgression is a key factor of barrier island (or coastal barrier) rollover, which occurs as overwash events become more frequent due to increasing water levels. Barrier rollover tends to steepen the beach face and create gentler slopes in the back-barrier environments as a result of material being eroded from the former and deposited in the latter. An evidence of coastal rollover during transgression is the exhumation of peat and lagoonal muds at the beach face (Fig. 3g). Peat and lagoonal muds form in relatively sheltered conditions (e.g., coastal embayments or back-barrier environments) where halophytic vegetation (e.g., saltmarshes) develops and fine sediments accumulate. Washover fans (Fig. 3c) are usually found in the upper beach or behind dunes, an indication of the material that was removed from the beach resulting in the exposure of the relict deposits.

The morphological change that will result from sea-level rise and the rate of change depends on processes acting at a range of scales (FitzGerald et al. 2008). Barrier islands may move inland tens of kilometers over thousands of years, but this process depends on successive overwash events to continue acting (each individually at much shorter scales) over the long time frames of barrier rollover. Barrier breaching and segmentation are also expected to occur due to sediment loss and impact of major storms, and barriers sometimes disappear due to subsidence.

In a transgression, coastal environments migrate inland to occupy their preferred position within the tidal range (Fig. 5a, b). As saltwater penetrates further inland, coastal wetlands, such as mangroves and saltmarshes, will start colonizing new areas, substituting grasslands and other vegetation not adapted to saline waters. If sediment is available, coastal wetlands are able to keep up with moderate rates of sea-level rise through vertical accretion. Where there is a sediment deficit, sea-level rise will outpace vertical accretion, and intertidal habitats may be lost as they become increasingly or permanently submerged. Some species occupy specific positions within the tidal range and may be lost due to increased duration and frequency of inundation. A similar effect will occur if further inland, topography is higher or gradient is steeper; in these cases, the horizontal distance between the high and low water line will reduce through time, resulting in smaller intertidal areas (Fig. 5c). The loss of intertidal habitats may result in erosion due to the direct release of sediment previously retained by vegetation and a reduction in the sheltering effect caused by the vegetation.

Coastal retreat or marine transgression may not be observed everywhere, even when sea level is rising. Marine regression (i.e., seaward displacement of the shoreline) will occur in areas where the rate of sediment accumulation outpaces the rate of sea-level rise (i.e., reducing the accommodation space). Increases in sediment supply arriving at the coast may be a consequence of sea-level rise or other factors. For example, sea-level rise may (a) change the base level of rivers, triggering an increase in fluvial sediment input to the coast, or (b) expose alluvium deposits to wave erosion creating a source of material to adjacent areas.

Human-Induced Coastal Erosion

Human activities have altered landscapes and the balance of natural processes in many ways and locations. Coastal erosion may result from activities taking place at the coast or further inland, causing cascading effects across temporal and spatial scales. These effects are so widespread and have been in place for so long that it may be difficult to separate the human and the natural contribution to coastal erosion. This differentiation is a complex task due to two main reasons: (1) coastal change results from the interaction of many factors which are naturally highly dynamic; and (2) our understanding of these

Erosion of Coastal Systems,

Fig. 5 (a) The distribution of some coastal habitats (e.g., saltmarshes) is dependent on the elevation in relation to the tidal levels. (b) Seeking to occupy optimal elevations within the tidal range, coastal habitats tend to migrate inland as a response to sea-level rise. A reduction in intertidal area may occur when the landward migration is prevented by (c) high topography or (d) the presence of coastal engineering structures. (e) Managed realignment increases intertidal areas allowing for the development of intertidal habitats by artificially breaching or removing of coastal defenses. (Adapted from Esteves 2014)

interactions is impaired due to poor data availability (e.g., short-time series, limited spatial and temporal resolutions, poor geographical coverage). Often, the ultimate cause of human-induced coastal erosion relates to direct and indirect impacts on sediment supply and distribution. However, in some cases, the key impact may be due to changes in relative water levels (e.g., land subsidence). The intension here is to provide just a few examples that illustrate the widespread human contribution to coastal erosion across a range of scales.

Erosion in coastal areas adjacent to river mouths is often linked to reduction of sediment reaching the coast due to retention within reservoirs built along the river course. This is probably the anthropogenic interference that alone creates

the largest reduction of sediment supply to coasts worldwide. A global study using a combination of measurements and modeling estimates that (a) dams built in the past five decades are retaining over 100 billion metric tons of sediment, (b) about 26% of the total sediment flux is retained in reservoirs, and (c) this retention results in a net reduction of 1.4 ± 0.3 billion metric tons per year in the flow of sediment reaching the world's coasts when compared to prehuman times (Syvitski et al. 2005). These results include the increase in fluvial sediment load due to deforestation and poor soil management practices in catchment areas. In river-dominated deltas, retention of sediment in dams can greatly enhance the problem of land subsidence and local effects

of hard engineering structures, as reported in the Nile delta (e.g., El Banna and Frihy 2009). River diversion, water abstraction, and other activities that reduce sediment supply to the coast will also contribute to coastal erosion.

Extraction of sand and gravel from the beach or nearshore for construction works (including beach nourishment) can cause a direct impact in local sediment availability and an indirect impact by increasing the wave energy reaching the coast (due to increasing depth). At present, in most locations, such activities are regulated and would not be allowed if there is a risk of detrimental impact (usually identified through environmental impact assessment). For example, in the Philippines, the government act Batas Pambansa Blg. 265 approved in November 1982 prohibits the extraction of sand and gravel from beaches to prevent erosion or impact on their “natural beauty.” In the island of Jersey (in the English Channel), a similar law passed in 1963 prohibiting extractions of sediment (from clay to gravel) from beaches and rocks forming the coast, except under license from the government. However, in some locations, the impact exists either because these regulations have not yet been implemented or arrived

too late or illegal extraction still takes place. More information on sediment mining impacts in coastal systems can be found in the Coastal Care website (Sand mining, <http://coastalcare.org/sections/inform/sand-mining/>, last accessed on 18 Jan 2018.).

Stabilization of cliffs and bluffs aims to slow down cliff retreat but can lead to beach erosion due to a reduction in sediment supply. Revetments and seawalls are commonly used to protect the base of cliffs and bluffs from wave action. Structures parallel to the coast, such as revetments and seawalls, are known to cause beach lowering due to scouring and removal of sediment due to wave reflection. This effect occurs when the water level allows waves to reach the structures and becomes more critical if occurring frequently. The integrity of revetments or seawalls can be threatened if sediment deficit results in continued beach lowering. Therefore, by preventing cliff erosion, these structures create a positive feedback that enhances beach erosion and, ultimately, requires the implementation of a number of hard engineering structures with mixed results. In Suffolk (east England), a myriad of coastal protection works (Fig. 6) have been implemented over the last

Erosion of Coastal Systems, Fig. 6 Examples of cliff stabilization along the Suffolk coast (east England). In the village of Thorpeness, (a) a revetment from the 1970s was exposed by a storm in the summer of 2010, leading to the addition of (b) geobags that were also exposed by another storm in 2013; enhanced cliff erosion is observed north of the revetments (where profiles shown in Fig. 4 were measured). (c) Seawall,

rock revetment, and fishtail groyne (which replaced old wooden groyne) after increased cliff failure in 2013 in Hopton, where the beach no longer exists at high tide. (d) In Corton, 2 km south of Hopton, since the 1890s, different coastal protection works have been built in an attempt to slow down cliff retreat

100 years in an attempt to halt retreat of the soft cliffs with little avail. In addition to the reduction in sediment supply resulting from cliff protection, there is a general perception in the local communities that other human activities have accelerated erosion. For example, erosion at Hopton (Fig. 6c) is said to have worsened due to works at the Great Yarmouth harbor, 3 km to the north. In 2013, cliff failures at Hopton resulted in the construction of fishtail groynes, which in turn created fears of increased erosion 2 km to the south at Corton (Fig. 6d), where local residents are pledging for similar structures to be built along their coastline.

Besides lowering beach levels, stabilization of coastlines by hard engineering structures can result in coastal squeeze. Coastal squeeze is the loss of intertidal habitats due to rising sea levels along coastlines fixed by hard engineering structures (Fig. 5d). As explained previously, intertidal habitats tend to migrate inland following a rise in sea level (Fig. 5b). Similar to the effect of raised topography (Fig. 5c), engineering structures can prevent this migration and reduce the area for intertidal habitats to develop, resulting in coastal erosion, particularly due to vegetation loss. Managed realignment involves breaching or removal of coastal structures allowing tidal inflow into previously embanked land increasing space for intertidal habitats to develop (Fig. 5e). Managed realignment is increasingly being implemented in Europe as a more sustainable approach to achieve both environmental and coastal protection enhancements (Esteves 2014). In some cases, sea-level rise can facilitate the development of saltmarshes within embanked land, without active intervention (i.e., passive habitat restoration). In south Portugal, salt-water intrusion is enabling the colonization of saltmarshes in embanked reclaimed land where agricultural practices have been abandoned since the mid-1960s (Almeida et al. 2014).

Obstruction of the littoral drift is a well-known and widespread effect of coastal engineering structures extending into the surf zone, such as groynes and jetties. The sediment transported by longshore currents is retained in the updrift side of these structures, causing a sediment deficit and erosion downdrift. Inlets are stabilized to improve navigation safety

and, paradoxically, reduce erosion caused by inlet migration. Groins are built either to redistribute sediment, forcing accumulation to occur where desired, or to reduce the rate of erosion due to longshore transport (e.g., prolonging the lifetime of beach nourishment). Inlet stabilization and maintenance of navigation channels bring enormous economic benefits (transport of goods and people, tourism). Mitigating measures can reduce but do not eliminate the impact of these structures on sediment budget. The Tweed River Entrance Sand Bypassing Project (Tweed Sand Bypassing, <http://www.tweedsandbypass.nsw.gov.au/>, last accessed on 18 Jan 2018.) (Australia) is an example of an inlet management plan based on sand bypassing (Fig. 7a) that has been reasonably successful in maintaining navigation safety and restoring the amenity of beaches to the north along the southern Gold Coast. Sand bypassing involves moving sand from accreted beaches to nourish eroding beaches.

In Florida (USA), it was estimated that 72% of eroding beaches are adjacent to tidal inlets (Esteves and Finkl 1998), and near inlets (within 3.6 km on average) magnitudes of shoreline change tend to increase (Absalonsen and Dean 2011). Florida has a large number of inlets; most are stabilized by jetties. As a result from sand being retained updrift of jetties and lost to offshore areas due to dredging of navigation channels, a critical sediment deficit developed, especially in southeast Florida. The need for sand bypassing became crucial to manage beach erosion. In 1986 Florida legislation recognized the issue and passed the “Declaration of public policy relating to improved navigation inlets” (Section 161.142), which established that beach-quality sand should be bypassed to downdrift beaches on an annual basis in volumes equivalent to the net annual longshore sediment transport. The legislation has stimulated the implementation of sand bypassing measures (Fig. 7b, c) as part of inlet management plans, but compliance has been an issue.

In the past, coastal erosion induced by human activities was a result of poor understanding of both the environmental impacts these activities would cause and the temporal and spatial scales of coastal change. Knowledge on these two

Erosion of Coastal Systems, Fig. 7 Examples of sand bypassing systems. (a) Tweed River Entrance Sand Bypassing Project (Australia) uses underwater pumps to move sand from the accreting beach south of the inlet to the beaches further north in southern Gold Coast. (b) This fixed dredge at the South Lake Worth (Palm Beach County, Florida)

bypassing sand accumulated north of the inlet to the eroding beach in the south since 1937. (c) The resident floating dredge at Hillsboro Inlet (Broward County, Florida) bypasses sand from a sand trap inside the inlet to nourish the eroding beaches north of the inlet; a weir jetty (seen beyond the dredge) also contributes to sand bypassing

fronts has greatly improved, and many activities known to have detrimental impact on coasts are now being prohibited or reversed. Examples are varied worldwide and include bans of new hard engineering structures, removal of coastal protection works, and removal of dams. Many projects now exist that prioritize the renaturalization of coastal areas, rivers, and floodplains (e.g., through managed realignment) to improve coastal erosion and flood risk management with added environmental benefits. The twentieth century (and earlier in some locations) can be described as the era of engineered coastlines, which resulted in extensive interference in the natural functioning of coastal systems. The realization about the level of impact of such interferences has gradually led to shifts in management practices, which may see the twenty-first century to become the start of a de-engineering era aiming to restore the dynamic nature of coastlines.

Summary

Coastal erosion is both a natural process important for the maintenance of dynamic equilibrium of coastal systems and a major hazard to human occupation along dynamic shorelines. Most often, it results from a combination of natural and human-induced factors acting at a range of scales. The importance of each specific factor will vary geographically and will depend on the temporal scale in which the system is being analyzed. Considering natural processes, erosion is often a temporary state associated with phases of natural cycles that can vary from short (e.g., seasonal increase in wave energy) to very long durations (e.g., sea-level rise during interglacial periods). Poor understanding about the duration of these cycles or about the spatial scale of associated coastal changes has led to human interferences that often result in enhanced erosion. Human-induced erosion is becoming pervasive worldwide both due to *in situ* direct impacts (e.g., due to coastal engineering works) and indirect impacts of inland activities (e.g., retention of sediment by dams). In many locations, climate change may result in increasing storminess and sea-level rise, which are likely to enhance existing coastal erosion or trigger a shift toward erosion. This is a particular concern where urban areas or coastal infrastructure is occupying dynamic spaces (areas where natural coastal change is expected) in low-lying coasts. There is a growing trend toward renaturalization of coastal areas (e.g., managed realignment) as a more sustainable approach to manage flooding and erosion risks with added environmental benefits. However, a key challenge to coastal management remains the urgent need to ensure that existing issues are not made worse by ill-informed policies or management decisions driven by short-term gains (e.g., allowing occupation in erosion-prone areas or persisting with hardening of shorelines where other options, including retreat, are more sustainable albeit more complex).

Erosion Processes

Michael R. Rampino

Earth and Environmental Science Program,
New York University, New York, NY, USA

Erosional processes along coastlines include: (1) the direct effects of hydraulic action, wedging, and cavitation by waves; (2) abrasion (corrasion), using sand, gravel, and larger rock fragments as tools; (3) attrition of the rock particles themselves during this abrasive action; (4) salt weathering or fretting; (5) erosion by organisms (bioerosion); and (6) chemical attack, or corrosion, which weakens the rocks and accelerates erosion. The rates of erosion by these processes are a function of the exposure of a coast to wave attack (wave energy and length of time of exposure), and the resistance of the materials to erosion and weathering.

Waves are the most dominant force causing coastal erosion. Ocean waves typically break at depths that range from about 1 to 1.5 times wave height. Because waves are seldom more than 6 m high, the depth of vigorous erosion by surf is usually limited to from 6 to 9 m below sea level. This theoretical limit is confirmed by observations of breakwaters and other coastal structures that are only rarely affected by surf to depths of more than 7 m. The change in water level caused by tides, however, allows waves to attack a greater range of elevations on the coast.

Wave impact directly exerts great pressure and can be a highly effective agent of erosion. The pressures produced by breaking waves have been measured by dynamometers, with reported values as high as 250 kg/m^2 ($6,000 \text{ lb/ft}^2$). These measurements agree with theoretical estimates (Gaillard 1904) based on wavelength and celerity. When the waves are long and their celerities are correspondingly high, the greatest pressures are generated.

When waves break against a cliff face, water is driven into cracks and joints and the air within the cracks is greatly compressed. The compressed air acts as a wedge, widening the fractures and loosening blocks of rock. As the wave recedes, the compressed air expands with explosive force (a process called cavitation), effectively quarrying out large blocks (Barnes 1956). Such quarrying action has provided enough energy to move blocks weighing many tons. There are many reports of the movement of large blocks by wave action, including a 2,500-ton piece of concrete at Wick (Scotland), and a section of a breakwater weighing 1,700 tons that was completely overturned at Bilbao (Spain).

Another method of marine erosion is abrasion, the mechanical wearing and grinding away of rock surfaces by the friction and impact of rock particles. Also called corrasion, this process involves the action of sand, gravel, and large

rocks picked up by the waves and driven back and forth against the exposed shore. Potholes can develop where large clasts are rotated by swirling water in the surf or breaker zone. The abrasion process includes dragging (friction), rolling, bouncing (saltation), and the artillery action of large fragments, which can shatter solid rock when hurled against a cliff. At Tillamook Rock on the Oregon coast, for example, rocks weighing as much as 297 kg have been picked up during severe storms and thrown through the windows of the light-house, 44 m above mean high water. Similarly, the windows of the Dunnet Head Lighthouse on the north coast of Scotland, more than 100 m above the high water mark, have been broken by rocks propelled by wave action.

Concentration of wave attack at the cliff base accelerates erosion and notches the base, permitting collapse or movement of the overlying material (Sunamura 1992). Seepage of ground-water (especially along seams and fractures), frost action, and wind combine with the under-cutting to produce cliff recession (Nott 1990). Differences in the resistance of the rocks being eroded and episodic collapse may produce an irregular cliff face, subject to mass movements (Duperret et al. 2002; Benumof et al. 2000). The debris produced by cliff collapse is subsequently used in abrasion of the cliff base, and/or removed by wave action, allowing the wave attack to continue. Thus, cliff erosion is generated by two processes: notching at the base of the cliff by marine processes, and collapse and denudation of the entire cliff face by a combination of subaerial and marine processes (Duperret et al. 2002).

The rate of cliff retreat, combined with rock type, climate (especially rainfall) and vegetation will determine the nature of mass movement down the cliff face. An extensive examination of Japanese cliff erosion, found that long-term cliff retreat is logarithmically related to rock strength and unrelated to cliff height (Sunamura 1977, 1992). Benumof et al. (2000) also found that rock strength, rather than wave energy or slope, is the critical factor in coastal cliff retreat.

Mathematically, the major factors of basal erosion have been summarized in Sunamura's equation:

$$x = f(F_w, S_r, t),$$

where x is the basal cliff erosion rate, F_w is the wave induced force, S_r is the cliff material resistance, and t is the time. Belov et al. (1999) developed a mathematical erosion function (the so-called Belov–Davies–Williams (BDW) equation) which accounts for erosion forces and the strength of the rocks, and also for the exponential decrease in wave erosion intensity with height. Numerical models have been quite successful at simulating basal cliff erosion (Belov et al. 1999).

The level of planation of the cliff base will usually lie immediately above the level of permanent rock saturation, where continued wetting and drying weakens the rock, allowing accelerated wave erosion. This level will, however, vary depending

on wave energy, rock type and structure, platform width, and accompanying atmospheric processes (Stephenson and Kirk 2000). The abrasion along the shore works horizontally to form a wave-cut cliff and a wave-cut platform. Exposure may be an important factor, as studies of shore platforms in Japan have shown that the mean platform width is about 40 m on the sheltered Inland Sea, 50 m on the more exposed Japanese Sea, and 60 m on the exposed Pacific coast (Trenhaile 1997).

Attrition is the process of wearing down by friction, involving the abrasion, impact, and grinding together of clasts in motion, resulting in smaller and usually better-rounded particles (in Europe, abrasion is used as a synonym for attrition). The impact and rubbing together of the rock fragments during wave action, as well as the grinding of the blocks that fall as the cliff is undercut, cause the tools themselves to wear down to smaller sizes and become rounded. Studies of attrition of beach clasts include experiments and observations in natural settings. Kuenen (1964) experimentally correlated rate of attrition with relative resistance and median clast size. Early comparisons of natural sediment distributions were done by Landon (1930), but lack of control makes the conclusions questionable. The observed diminution of grain size along a coast could be also due to change in source material or to sorting by longshore transport.

Salt weathering or fretting takes place when salt crystals grow within pore spaces in rocks; the crystal growth expands the pore and may lead to fracturing of the rock (Wellman and Wilson 1965; Mottershead 1989). This may be the result of strong evaporation that draws salt solutions to the surface by capillary action. The salt-weathering process is most effective in areas exposed to salt spray and subject to alternative wetting and drying. Salt weathering can also produce a honeycomb pattern in the rocks called tafoni, which is most characteristic of tropical and subtropical semiarid to moderately arid climates. In chalk cliffs, basal notching has been attributed to salt weathering and repeated wetting and drying cycles (Duperret et al. 2002).

The chemical and solvent action of seawater may be especially important along limestone and chalk coasts. On some atolls, solution may be responsible for 10% of total erosion of the coast (Trenhaile 1997). However, even non-calcareous rocks may weather more rapidly as a result of the chemical action of seawater. In some cases, chemical dissolution and salt fretting may act together.

Additional factors that may contribute to mechanical weathering in certain areas include large diurnal temperature variations and biological activity. Weathering due to temperature variations mainly affects the surface layers. The temperature distribution in rocks is non-uniform, and differences in rock composition yield thermal conductivity contrasts and large temperature gradients. This can cause thermal cracking of blocks, resulting in displacement along existing joints and fractures.

Biological erosion is especially important in tropical or subtropical areas having limestone coasts. Algae are probably the most important bioerosional agent on rocky coasts. The substrate under algal mats is exposed to the products of metabolism and organic waste, which can directly etch the rocks. Algae also support grazing organisms such as gastropods and echinoids, which abrade rock surfaces. Bioerosion, combined with the chemical solution of limestone by algae, produces the intricate scalloping known as phytokarst (Bromley 1978). Boring and browsing organisms erode rocks most effectively in the inter-tidal zone, and bioerosion can eventually weaken the framework of reefs to the point where collapse takes place. Rates of bioerosion on horizontal and vertical limestone surfaces have been estimated at about 0.5–1 mm per year (Trenhaile 1997).

In cold regions, where unconsolidated but frozen, ice-bonded sediments are exposed to wave erosion, convective heat transfer between seawater and the melting surface of the frozen cliff sediment (thermal abrasion) combines with erosive wave action and slope failure to under-cut cliffed coasts (Kobayashi et al. 1999). Wave erosion removes the unfrozen sediment, which would insulate the frozen sediment from further melting. The combined thermal and mechanical processes can lead to rapid erosional retreat (>1 m per year) during periods of open-water conditions. Tidally induced frost action occurs in the inter-tidal zone where rocks freeze when exposed to air and thaw when covered by the rising tide. This mechanism is particularly effective because of the frequency of freeze–thaw cycles. In coastal Maine, for example, there are an average of 133 freeze–thaw cycles each year in the inter-tidal zone versus only 30 or 40 cycles inland (Trenhaile 1997).

Definition

Historical erosion rates are determined by monitoring the location of a representative shoreline reference feature, along a prescribed shore-parallel distance, over a specified time frame. Shoreline reference features, such as the high water line (HWL), are digitized from historical maps and aerial photographs, and combined with more recent shoreline data obtained from sources such as Light Detection and Ranging (LIDAR) and Global Positioning Systems (GPS) surveys. In the USA, the use of historical National Ocean

Service (NOS) T-sheets often allow erosion rates to be determined over a period of 150 or more years. Long-term erosion rates are valuable for coastal land use planning in that they can be used to predict coastal areas susceptible to future erosion.

Introduction

The study of long-term coastal erosion has taken on increased importance as development along the world's coasts has risen dramatically over the past several decades. This is readily apparent, for example, in the United States where development has transformed many small beach villages into moderately to densely populated cities. This has resulted in increasing population at risk from coastal hazards, such as hurricanes, nor'easters, and tsunamis, and associated damages from wind, coastal flooding, and erosion. Almost 30% of the US population lives in "hurricane prone regions" (Crowell et al. 2010) as defined by the American Society of Civil Engineers (ASCE 2006). In addition, almost 3% of the US population lives in ocean and Great Lakes coastal flood hazard areas defined by the 1% annual chance flood (Crowell et al. 2013). A subset of this coastal flood-prone population is also subject to the risk of long-term erosion.

Erosion rates (The phrase "erosion rate" is used throughout this article as an equivalent to the more precise "recession rate." Long-term beach recession is caused by a combination of long-term "static" inundation from rising sea levels combined with long-term "dynamic" erosion) are calculated by monitoring the location of a representative shoreline reference feature or proxy, usually the high water line or bluff line, over a specified time frame. Rates are obtained by measuring the location of two or more shorelines from historical shoreline change maps. These maps are produced by digitizing shoreline change reference features from historical maps and aerial photographs, and combining and registering these data with more recent shoreline data from LIDAR, and GPS surveys. Historical shoreline change maps and datasets for the USA often contain four to eight or more shorelines and can span 150 or more years. Erosion rates are typically calculated from the maps by generating a line perpendicular to the multiple shorelines and measuring the amount of movement over a period of time defined (and constrained) by the dates of the digital shorelines.

Sources of Historical and Current Shoreline Location Data

There are four principal data sources used in the production of historical shoreline change data: historical maps, recent and

historical aerial photography, LIDAR surveys, and GPS surveys. Following are brief descriptions of these sources.

Historical Maps. In the United States, the primary historical map data source is NOS T-sheets. The first T-sheets date back to 1835, but maps of 1835 to 1845 vintage sometimes show inaccuracies in longitude. In 1846, NOS surveyors began using the telegraph as part of field mapping which significantly improved longitudinal accuracy to the point that maps of post-1846 vintage are typically accurate enough for use in modern historical shoreline mapping studies. NOS has periodically remapped coastal areas every 20–60 years. As such, two or three pre-1940s and one to two post-1940s T-sheets are generally available for most of the US East and Gulf Coasts (Anders and Byrnes 1991).

NOS T-sheets are an invaluable data source that expands the temporal range of the historical shoreline data from about 75 years (using only aerial photography, and/or GPS ground surveys and LIDAR) to 150 or more years. A major prerequisite, however, is that each map be rectified and corrected for error factors such as scale differences, rotation, and uneven map shrinkage. Map scale is obviously a major consideration – 1:10,000 or larger is preferred, although maps at scales as small as 1:20,000 are often usable (Anders and Byrnes 1991; Moore 2000).

Aerial Photographs. Vertical aerial photographs date back to the 1920s; however, aerial photography produced prior to the late-1930s is typically overly distorted and of insufficient resolution for use in historical shoreline mapping studies (see below). Moreover, it was not until after World War II that air photos on the US coasts were taken with any degree of regularity. Many of these sets of aerial photography were taken to document storm impact and, as is discussed later, are of questionable use for determining long-term rates of beach erosion (Douglas et al. 1998). Nonetheless, several sets of post-World War II aerial photographs suitable for historical shoreline mapping studies are often available for a given area.

GPS Surveys. Field-based surveys using GPS have been increasingly used within the past few decades (Morton et al. 1993; Hapke et al. 2011). Shoreline position data are collected by driving a GPS-equipped off-road vehicle directly along a shoreline reference feature, such as the HWL. Geo-coordinates are collected at specified intervals, enabling real-time digitization of the shoreline reference feature.

LIDAR Surveys. LIDAR technology is now routinely used to conduct beach mapping, including the updating of historical shoreline change data (Robertson et al. 2004). This technology is being extensively used by the United States Geological Survey (USGS) in their national shoreline mapping project (<https://marine.usgs.gov/coastalchangehazards/research/long-term-change.html>). The LIDAR sensing instruments only collect elevation data, which can be related to the mean high-water (MHW) shoreline (Hapke et al. 2011).

These aircraft-acquired data are of very high resolution with a vertical precision of 15 cm or better as verified by GPS kinematic beach surveys (Middleton et al. 2013). A large stretch of beach can be imaged in a few hours, providing coastal scientists and resource managers the capability of producing high-resolution beach maps much faster and less expensively than traditional beach mapping (<http://geodata.lib.ncsu.edu/fedgov/noaa/commvuln/htm/intro.htm>).

Special Note on Drone Technology. The advent of drone technology is revolutionary in its capability to conduct mapping using a high-resolution video-camera with still-frame capability. LIDAR units are now so light and small that they can be carried aloft by a quadcopter-type drone (<https://www.dronezon.com/learn-about-drones-quadcopters/best-LIDAR-sensors-for-drones-great-uses-for-LIDAR-sensors/#>). Measurements extending several kilometers can now be undertaken, and the range can be increased by using very short laser pulses in the invisible near-infrared; this enables higher laser power compared to continuous wave lasers.

Shoreline Change Reference Features (Proxies)

A number of potential shoreline reference features or proxies can be used to monitor historical shoreline changes (see, for example, Boak and Turner 2005). In many situations, the HWL has been shown to be the best indicator of the land-water interface for long-term historical shoreline comparison studies, especially those that incorporate NOS T-Sheets, as the HWL was the boundary line mapped by early NOS topographers. The HWL is usually easily recognizable in the field, it can often be approximated from air photos (Stafford 1971), and it represents a shoreline feature that has been mapped (albeit sporadically) since the mid-1800s. There are several factors, however, that must be considered or addressed when using the HWL as the representative shoreline proxy. For example:

- Variability of the HWL location must be considered. As an example, Dolan et al. (1980) monitored the short-term variability of the location of the HWL during a tidal cycle in NC and VA. He found that the position of the HWL could vary anywhere from 0.12 m to 5.8 m.
- Correct identification of the HWL is critical. Pajak and Leatherman (2002) found that other shoreline indicators, such as the swash terminus, can easily be mistaken for the HWL on poor-quality aerial photographs.
- LIDAR surveys can present inconsistent comparisons of shoreline reference features, as these datum-derived MHW shorelines are typically offset seaward from the HWL (Morton et al. 2004).
- The HWL is not always the most representative proxy for long-term shoreline movement, particularly in areas with

gently sloping beaches or where rates of erosion are low (Morton et al. 1993). In these and other situations, Morton notes that other morphological features, such as erosion scarp, crest of washover terrace, or vegetation line are more diagnostic of long-term change than the HWL. Use of these other indicators, however, severely limits the temporal span of source data.

For cliffed situations, the top edge of the bluff (employing the terms cliff and bluff interchangeably) is commonly used as a shoreline change proxy. Unfortunately, historical maps depicting accurate bluff positions are rare, thereby limiting historical source data to the temporal span covered by aerial photographs, and GPS and LIDAR surveys (e.g., 1930s to present). Other features are sometimes used to monitor historical bluff change. The State of Wisconsin, for example, has experimented with the mid-bluff contour, with the rationale that the middle of the bluff is typically the most stable portion of the slope because it is located below areas subject to frequent failure and above the associated debris or talus pile (Crowell and Leatherman 1999).

Rectification and Registration of Historical Maps and Aerial Photography

In order to use historical maps (such as NOS T-sheets) and aerial photographs in historical shoreline change exercises, one must be able to register these data to the same coordinate system used by other data sources, such as GPS and LIDAR surveys. At the same time, errors and distortions must be corrected. The methods for registering and correcting historical maps and aerial photographs have their differences.

Historical Maps. To register historical maps to a specific coordinate system, one must identify a number of permanent and stable points or features on the map for which accurate and current geographic coordinates are known. The features are known as primary control points. For computer applications, a minimum of four primary control points are required, although six to eight points are commonly used to improve accuracy and aid in error analysis. These points are used to calculate the transformation necessary to change from one coordinate system to another and to correct for error factors such as scale differences, rotation, and uneven map shrinkage. Selection of primary control points is trivial if the source map contains current geo-coordinates, such as latitude and longitude tick-marks. However, historical maps often have latitude-longitude lines based on obsolete datums. For example, latitude-longitude coordinates for US maps produced prior to 1927 must be updated to better standards such as the North American Datum of 1927 (NAD27), or preferably the more recent NAD83. If latitude-longitude coordinates are not available for the map or if the coordinates are present but with an

unknown datum standard, then other techniques must be used to update the map. One very useful technique is to search the map for survey stations or hard permanent features for which modern coordinates are known. In the case of NOS T-sheets, several triangulation stations are usually mapped for which current coordinates can be obtained (Crowell et al. 1991).

Aerial Photography. Since 1927, aerial photography and photographic methods have been used to provide topographic information along the coast, creating an important dataset for use in historical shoreline change studies. Air photos, however, are not map projections; corrections for distortion due to tilt, tip, and yaw (and sometimes relief) must be made prior to and/or concurrent with the compilation process so that shoreline positions obtained from air photos can be compared to those compiled from planimetric maps, GPS, and LIDAR surveys. Several computer programs are available that automate air photo rectification in a process called “soft-copy photogrammetry” (Moore 2000). The process involves creating photomosaics prepared from scanned and rectified aerial photographs. A series of ground control points are used to spatially reference the imagery to geo-coordinates. Pass points, which are identifiable landmarks common to two or more photographs (but not ground controlled), are supplemental and serve to reference the photos to each other (Coyne et al. 1999). In summary, the rectification process transforms the imagery to a map projection and corrects or minimizes map distortions, such as tilt, scale differences, relief displacement, and radial lens distortion.

Accuracy of Source Data

Accuracy of source data has been discussed in a number of publications (Shalowitz 1964; Morton 1974; Dolan et al. 1980; Leatherman 1983; Everts et al. 1983; Anders and Byrnes 1991; Crowell et al. 1991; Thieler and Danforth 1994; Gorman et al. 1998; Moore 2000; Hapke et al. 2011; Wernette et al. 2017). In general, most researchers acknowledge that historical shoreline maps and historical aerial photographs (combined with more recent LIDAR and GPS surveys), provide an important source from which to monitor shoreline movement and calculate rates of change.

NOS T-Sheets and Aerial Photography. Questions regarding accuracy of older source data, particularly historical NOS T-sheets, spurred Crowell et al. (1991) to devise a way to determine the maximum errors and measurement uncertainty one would expect to find using historical and current aerial photography and historical NOS T-sheets. Using rectification and registration methods described above, the authors approximated errors for each individual step in shoreline data compilation, including survey, digitization, mapping, and map and aerial photograph distortion. The square root of the sum of squares was used to obtain estimates of

measurement uncertainty in the digitized location of the interpreted shoreline (in this case, the high water line). Measurement uncertainties were calculated for the following data sources (all at 1:10,000 scale): 1846–1930 T-sheets prepared prior to the use of aerial photography: 8.4–8.9 m; post-1950s T-sheets compiled using aerial photography: 6.1 m. Crowell et al. (1991) also estimated measurement uncertainties of 7.5–7.7 m for aerial photography, albeit acknowledging that there is additional uncertainty resulting from misinterpretation of the HWL from poor quality aerial photography. These estimates were based on analysis of T-sheets and aerial photography from the northeast coast of the United States. Importantly, short-term process variability factors, such as daily and monthly tidal changes and storm effects, were not included in the error estimates. Comparable measurement uncertainties for T-sheets and aerial photography are presented in Hapke et al. (2011), who used similar statistical methods.

GPS Surveys. Field-based shoreline surveys using global positioning systems (GPS) have been used since the early 1990s (Morton et al. 1993). Shoreline position data are collected by driving an off-road vehicle equipped with a GPS unit directly along the HWL. Geo-coordinates are collected at specified intervals, allowing real-time digitization of the HWL. GPS surveys have an advantage over older plane-table, alidade, and rod surveys (as used, for example, by the field-based NOS topographers) in that there is little need to interpolate and sketch the HWL between rodded points. Indeed, GPS measurement of the interpreted position of the HWL are so accurate (within a meter) that measurement error is usually insignificant compared to the ambiguity inherent in the determination and identification of the HWL.

LIDAR Surveys. LIDAR surveys have an advantage in that it is possible to objectively determine the MHW shoreline based on tidal datums or elevation contours, rather than relying on an uncontrolled shoreline proxy, such as the HWL (Hapke et al. 2011). However, as noted by Morton et al. (2004) and Hapke et al. (2011), there are horizontal and vertical differences (offsets) in the location of the HWL determined from beach surveys, aerial photographs, and GPS surveys, as compared to the MHW shoreline determined from LIDAR surveys. The offsets can be assessed and corrected for by using methods described in Hapke et al. (2011).

Calculation of Long-Term Erosion Rates

A primary reason for calculating long-term erosion rates is for forecasting erosion hazard areas which are commonly used for land-use planning, ranging in purpose from providing information to property owners, to establishing regulatory setback lines for coastal construction. Usually building setbacks are based on the average annual erosion rate for the

area, multiplied by a specified number of years, typically 30 and 60 years. The computed setback is then measured landward from an erosion reference feature, whose movement would have the most impact on the structural integrity of a building. As such, the erosion reference feature is typically the top edge of a bluff, dune escarpment, vegetation line, beach scarp, or perhaps the HWL (The erosion reference feature for any given stretch of beach may not necessarily be the same feature or shoreline proxy used to determine the historical erosion rate). If the erosion rate at a site is, for example, 5 ft per year, then the 30-year setback is 150 ft and the 60-year setback is 300 ft, both of which would be measured landward from, for example, the top edge of the bluff.

The predictive accuracy and uncertainty of erosion forecasts have been discussed in a number of papers (Crowell et al. 1993; Crowell et al. 1997; Douglas et al. 1998; Galgano and Douglas 2000; Douglas and Crowell 2000; Honeycutt et al. 2001; Genz et al. 2007; Hapke et al. 2011; Fletcher et al. 2012; Del Río and Gracia 2013). While accuracy of the source shoreline data is paramount, there are other important matters to consider prior to calculating long-term rates of erosion. For example, a decision must be made regarding: (1) The temporal span of the shoreline data to be used in determining the rate – for example, short-term (<30 years), medium-term (30–60 years), or long-term (>60 years) data; (2) The statistical method or model that should be used to determine the rate – for example, end point rate, linear regression, modeling; and (3) whether certain shoreline data should be deselected from the historical shoreline change dataset.

Temporal Span. Crowell et al. (1993) and Galgano et al. (1998) demonstrated the importance of using data sets spanning 60–80 years or more to determine the long-term trend of erosion for forecasting future shoreline positions. Such long data spans are needed because the erosion/recovery cycle associated with severe storms can obscure the underlying trend of erosion for decades. However, in many cases, only the more recent sequences of historical shorelines should be used, particularly in areas where prolonged and perhaps permanent physical changes to the beach system have occurred (see below).

Statistical Methods. A simple method that is sometimes used by researchers and planners to calculate rates of erosion is the “end-point-rate” method. In this method, the analyst selects two representative shorelines, often the earliest and the most recent, to calculate the amount of shoreline movement. This distance is then divided by the time elapsed between successive shoreline positions. The advantages of this technique include simplicity in application and two shorelines suffice to obtain a rate. A major disadvantage is that the position of one or both of the endpoint shorelines may be aberrant, and so the rate of change can be misleading for use in determining future shoreline positions. Moreover, data between the end points, of value in determining the rate of

change, are not used and hence potentially useful information is ignored.

Another method popular among researchers is the use of linear regression. With this method, a best-fitting straight line is determined that minimizes the sum of the squares of the lengths of vertical line segments drawn from the individual data points to the fitted line. The advantages of this method are that: (1) all data points (except for poststorm shorelines) are used in the rate calculation, thereby reducing the influence of spurious data points; (2) linear regression is an easily understood statistical analysis tool that can be performed with most spreadsheet programs, and (3) summary and related statistical techniques are available to test and measure the quality of the straight-line fit and estimate the variance of the data (Kleinbaum and Kupper 1978). Other empirically based statistical methods have been proposed to calculate long-term erosion rates, but because of the scarcity and uneven sampling of the data, it is debatable whether these methods improve on the forecast (Crowell et al. 1997).

Deselection of Historical Shorelines. A decision whether to deselect certain shoreline datasets a priori is critical in determining a realistic historical erosion rate as certain historical shorelines may not be representative of the long-term trend. As an example, because of large seasonal fluctuations in beach width (particularly in the non-summer months), only summertime data should be used in historical shoreline change analyses (Zhang, et al. 2002). This is especially true when using historical NOS T-sheets in the shoreline change analysis, as T-sheets were almost always mapped during summer beach conditions. Combining a sequence of older “summer beach” NOS T-sheets with a sequence of more recent “mixed season” imagery/GPS shoreline data could lead to results biased towards higher rates of long-term historical erosion or lesser rates of long-term accretion. In addition, the emplacement of a major shoreline engineering structure (e.g., groins, jetties, and seawalls) may have a demonstrable long-term effect on the beach and make older

data unrepresentative of the long-term trend. Similarly, a major storm could open up an inlet, thereby altering the long-term trend on nearby beaches. In these situations, it may be prudent to deselect older, pre-event shoreline data.

A related question is whether immediate poststorm shoreline imagery should be included in the historical shoreline datasets. Insight into this question can be gained from the following example of an actual history of shoreline positions. Consider the data shown in Fig. 1 (after Douglas and Crowell 2000). The graph shows ten shoreline positions from 1845 to 1997. The shoreline location data are from the Atlantic coast of Delaware, just south of the Indian River Inlet near a location called Cotton Patch Hill. The 1929, 1962, and 1963 shoreline positions were photographed or mapped immediately following major storms and are shown as red circles on Fig. 1. Note that these three poststorm shoreline positions are inconsistent with the long-term trend line determined from the other seven shoreline positions. During a large storm, more erosion can occur in a few days than in the previous 50 years, which is often followed by an extended period of beach recovery. Note that accretion continued after the 1962 Ash Wednesday nor’easter for at least a decade. Therefore, determination of the long-term rate of beach erosion should not be undertaken without consideration of the role of severe storms on shoreline position.

The example above also serves to illustrate the proper statistical approach to the shoreline position forecasting problem. A correct methodology requires that the forecast model be in reasonable agreement with the actual physical situation. Figure 1 shows that there was a long-term trend of beach erosion, superimposed with episodes of severe erosion followed by extended periods of recovery. Use of poststorm shoreline positions in determination of the long-term trend will yield aberrant results.

Erosion: Historical Analysis and Forecasting, Fig. 1 Beach Erosion History at Cotton Patch Hill, DE

Newer Methods and Addressing Sea Level Rise

The above statistical methods for determining long-term erosion rates and future shoreline locations typically assume stationarity; that is, the forecasted rate of shoreline change is assumed to be linear and equal to the historical linear rate of shoreline change. As such, the method does not consider potential acceleration or deceleration caused by geophysical processes, such as changes in the rate of relative sea level rise. Long-term sea level rise, however, is an “enabler” of long-term beach erosion. As sea levels rise, land is inundated by the rising waters, and higher water levels allow increasing erosion. Accordingly, the location of a receding shoreline is dependent on both sea level rise-induced static inundation combined with dynamic erosion. If relative sea level rise is projected to accelerate, then in most cases long-term erosion rates should also be projected to accelerate (TMAC 2015).

The best known model to link sea level rise with erosion is the Bruun Rule. The Bruun Rule is a two-dimensional model that predicts a landward and upward displacement of the beach profile in response to sea level rise (Ranasinghe et al. 2012). The Bruun rule, however, has long been controversial, and while it may be suitable for regional scale assessments, it is generally recognized as unsuitable for localized studies which require reliable estimates of shoreline retreat (Ranasinghe et al. 2012). Over the past few years, however, new methods and models have been proposed that predict future shoreline locations in which the influence of sea level rise is considered. For example, Romine et al. (2009) developed polynomial methods that consider acceleration (both increasing and decreasing) in order to provide additional information regarding how erosion rates may vary through time. Anderson et al. (2015) combined historical erosion rates with a Bruun-derivative model (from Davidson-Arnott 2005) that incorporates projected acceleration in sea level rise. Ranasinghe et al. (2012) have developed process-based models that provide probabilistic estimates of long-term recession that incorporates sea level rise. Finally, Gutierrez et al. (2011, 2014) used a Bayesian network to produce probabilistic forecasts of future shoreline locations assuming accelerated sea level rise (TMAC 2015).

Conclusions

Many difficulties can be encountered in accurately determining the long-term behavior of shorelines based on sparse data sets. The complexity increases if engineering changes (such as construction of groins or jetties) have been made to the shoreline or if tidal inlets are opened as a result of a large storm. In addition, capes and spits often display a complex episodic cycle of erosion and accretion that is unrelated to storms. Thus the highest-quality forecasts of long-term

shoreline position need to consider meteorological and geomorphic factors and the role they play in the evolution of the shoreline position.

Estuaries

Terry R. Healy

Earth Sciences Department, University of Waikato,
Hamilton, New Zealand

In the now voluminous coastal literature, the definition of “estuary” is highly variable, and frequently reflects the standpoint of the author. Pethick (1984) states that: “estuaries are among the largest and most complex of all landforms, so complex in fact that attempting to provide a basic definition has proved extremely difficult.”

Indeed one writer describes the definition of an estuary as rather like pornography – difficult to define, but you know it when you see it!

Central to the concept is that *estuaries are the tidal mouths of rivers* (Pethick 1984). The French geomorphologist Guilcher (1958) pointed out that the word estuary comes from the Latin *aestus*, meaning tide, but that in France it has a popular synonym, *etier*, and the two words denote that part of the river system where the tides (water level rise and fall) and tidal currents make themselves felt. This is essentially the definition adopted by Fairbridge (1980) who defined an estuary as: “an inlet of the sea reaching into a river valley as far as the upper limit of tidal rise.” This concept is also accepted by Caspers (1967) who argues that “the upper limit of the estuary is determined not by salinity but by tidal forces. In other words it is determined hydrodynamically rather than hydrochemically.”

Terry R. Healy: deceased.

Thus, in principle an estuary can be defined from several different perspectives, including from the point of view of the geomorphology, sedimentation processes, tidal influences, the physical oceanography/salinity structure, or the ecology. In simple terms the definition is perhaps best considered from the standpoint of either “form” or “function.”

From the geomorphic perspective, an estuary is defined in the general sense as: “the mouths of rivers, widening as they enter the sea” (Bird 1972). On a global scale they typically form in drowned river valleys. The Webster Dictionary (2nd edn) describes an estuary as “a passage, as the mouth of a river or lake, where the tide meets the river current; more commonly, a narrow arm of the sea at the lower end of a river.” However, the authoritative Glossary of Geology, edited by Jackson (1997) defines an estuary variously as:

(a) the seaward end or the widened funnel-shaped tidal mouth of a river valley where freshwater mixes with and measurably dilutes sea water and where tidal effects are evident; e.g., a tidal river, or a partially enclosed coastal body of water where the tide meets the current of a stream. (b) A portion of an ocean, as a firth or an arm of the sea affected by freshwater; e.g., the Baltic Sea. (c) a drowned river mouth formed by subsidence of land near the coast or by the drowning of the lower portion of a non-glaciated valley due to the rise of sea level.

In physical geography terms the Webster Dictionary (2nd edn) defines an estuary as: “a drowned river mouth, caused by the sinking of the land near the coast.” Stamp, in his *Glossary of Geographical Terms* (1966), defines an estuary as a “tidal opening, an inlet or creek through which the tide enters; an arm of the sea indenting the land,” but Stamp states that this definition is rare in modern use.

Cameron and Pritchard (1963) provide a definition of estuaries perhaps the most widely accepted by coastal scientists, as: “a semi-enclosed coastal body of water which has a free connection with the open sea and within which sea water is measurably diluted with fresh water from land drainage.” This definition appears in most of the modern textbooks such as Pethick's (1984): “*An Introduction to Coastal Geomorphology*” and Black (1986): “*Oceans and Coasts*.” Such a definition leads to a classification of estuaries as a function of their salinity structure, focusing on the oceanographic properties determined by the physical dimensions in relation to river flows, salinity distribution, and tidal conditions. Another influencing factor is the Coriolis effect which becomes important for wide estuaries. Based upon these physical characteristics, estuaries may be classified as follows (Bowden 1967): (1) *Salt wedge estuaries* occur where river flows dominate the salinity structure. In such cases, the river waters flow seawards as a layer of freshwater separated from the underlying saltwater by a sharp density interface. This reduces the turbulence and mixing between the two separate water bodies, and the saltwater extends as a down-sloping wedge along the bottom into the head of the estuary. (2) *Two*

layer flow with entrainment. Again two distinctive water bodies of different salinity and density are apparent in the vertical, but when internal waves at the interface break, salt-water is entrained upwards into the surface freshwater, thereby increasing its salinity. To compensate for this entrainment there is an upstream directed residual flow along the bottom. It is this current that facilitates transport of fine suspended material upstream into the upper reaches of the estuary. (3) *Two layer flow with vertical mixing*. In relatively shallow estuaries the turbulence generated by the tidal flows generates mixing through a greater proportion of the water body. Fresher water is mixed downwards and saline water upwards, but there is no sharp density interface boundary. However, there are still two layers of flow and a bottom landwards residual current. (4) *Vertically homogeneous estuaries*. When tidal currents are strong in relation to the freshwater input, or in shallow estuaries where form drag induces turbulence throughout the flow, the vertical mixing becomes complete throughout the water column, and there is no measurable variation in salinity from the surface to the bottom. There is, of course, a horizontal gradient of salinity from the estuary head to the mouth.

Wind may have an important influence on the estuarine density driven circulations. Wind stress on the water surface produces a net transport of surface water, and the waves generated increase the intensity of vertical mixing. These processes on occasions can override the normal estuarine density circulation.

Physiographically estuaries are of four identifiable types (Healy and Kirk 1982). These are: (1) *Fjords*, characterized as former valley glaciers in mountainous terrain, with steep sides, a deep basin, and in many cases a sill at its mouth. Such features occur in Norway, Scotland, southern Chile, and southwest New Zealand. But there are also more complex lowland fjords of the Baltic type, formed originally as meltwater depressions under the Pleistocene ice sheet, and flooded with the postglacial sea-level transgression. (2) *Drowned river valleys* or *rias* occur widely along mid-latitude coasts, and occur in their purest form as meandering river valleys along coasts with hard crystalline basement rocks with low sedimentation rates. In many cases, complete valley systems were drowned resulting in a dendritic pattern of arms. Along active sedimentation coasts the rias are often modified as they connect with the open sea, typically exhibiting sediment infill of the drowned river valley to form modern tidal flats (Fig. 1) and low alluvial plains developed over the estuarine sediments. They may possess barriers across the mouth of the embayment, such as occurs on the Oregon and New Zealand coasts (Fig. 2). Where major faulting occurs the rias may become fault-aligned as in New Zealand's Marlborough Sounds. (3) *Barrier enclosed estuarine lagoons* occur along the low sandy barrier coasts of the world, such as the Atlantic seaboard of the United States or the eastern coast of Australia (Fig. 3). The older term

Estuaries, Fig. 1 Drowned river valley with active infill sedimentation forming muddy tidal flats, Raglan Harbour, New Zealand (Photo: T. Healy)

Estuaries, Fig. 2 Estuary of the Waioeka River mouth, Bay of Plenty, New Zealand, illustrating a Holocene sandy barrier formation across the river mouth (Photo: T. Healy)

“bar built” estuaries is genetically misleading, and should be avoided, as few barriers originate from “bars.” The enclosing barriers typically comprise Holocene dune barrier-islands and spits as is typical along the Atlantic and Gulf coasts of the United States, but that is not always the case. Some enclosing barriers may comprise high (up to 200 m) Pleistocene dunes, as for the very large harbors on the west coast of the North Island of New Zealand, and sometimes the enclosing barriers may be of gravel, and even boulders, as for example at Nelson, New Zealand. These lagoonal-type estuaries are characterized by shallow depths and frequently broad expanses of intertidal flats become exposed at low tide. Where they occur along littoral drift coasts the entrances are characterized by narrow

tidal inlets with ebb and flood tidal delta systems. Because of the overall shallow lagoon, the estuaries are well mixed in terms of their salinity structure, although there may be salinity variation from the mouth to the head of the lagoonal estuary. In arid coasts, the lagoonal waters may become hypersaline. (4) *Structural and tectonically induced estuaries* are typified by downthrown grabens (San Francisco Bay), tectonic depressions (Botany Bay, NSW), or flooded calderas (Banks Peninsula, New Zealand). These tend to be large-scale features (Fig. 4).

Clearly, there is a geomorphic gradation both within and between large estuaries. For example, a large barrier-enclosed estuarine lagoon may possess arms in its upper reaches that

Estuaries, Fig. 3 The shallow estuarine lagoon of Maketu, Bay of Plenty, New Zealand, enclosed by a Holocene barrier spit. The entrance is a tidal inlet system (Photo: T. Healy)

Estuaries, Fig. 4 The down faulted structural graben of the Firth of Thames, New Zealand, into which flows the large Waihou River. The name “Firth” is a geomorphic misnomer, as this structural estuary did not originate from ice scour (Photo: T. Healy)

exhibit the geomorphic characteristics primarily of a drowned river valley, and salinity characteristics of a salt wedge and two-layer flow. Conversely, a drowned river valley estuary with overall dendritic outline may possess barriers across its mouth (e.g., Chesapeake Bay, or Raglan Harbour in New Zealand).

However, all of these geomorphic categories of estuaries feature an element of “drowning” from rise of the postglacial sea level, which reached its approximate present level some ~6,000 years ago (Russell 1967). However, continued drowning of an estuary is rarely identified in modern times, despite the present global warming and its consequent sea-level minor rise.

On the contrary, active sedimentation within estuaries overall outweighs any modern sea-level rise effect. This is

especially so for high sediment load major rivers such as the Amazon, the Yellow River of China, and the Mississippi, where rapid sedimentation and the growth of deltas has greatly modified the estuary over the past ~6,000 thousand years. Indeed, estuaries are well recognized as natural sediment traps, and are ephemeral features of the geological record. As Russell notes, most estuaries have changed considerably from the active sedimentation during the past few millenia, and many estuaries are headed for extinction. Rapid sediment input into estuaries from the inflowing river catchments, acts to fill them up from the land. But (especially for lee coast estuaries) diabathic onshore transport across the shelf provides sediment at the coasts that sweeps into the estuary mouths, and acts to infill estuaries from the sea. In addition,

the saline density circulation within estuaries and mixing of mud-laden freshwaters from the catchment with the saline marine waters, leads to flocculation of fine particles, which residual bottom currents tend to transport toward the head of the estuary, where the muds deposit and accumulate.

Within most estuaries tides are the major energy source for mixing fresh and saltwater, and for resuspending sediment from the bed and transporting those sediments seawards or landwards. Frictional effects dissipate the tidal wave energy within the estuary, and deform the tidal wave. But this is offset by convergence of the tidal wave as it progresses up the estuary. Depending upon the balance between tidal wave convergence compared with frictional dissipation effects, the tidal range within an estuary can be larger than at the open sea before decreasing landwards toward the river (a hypersynchronous condition), or the frictional effects can dominate and the tidal amplitude decreases landward from the mouth, a hyposynchronous condition. Most ria type estuaries are a hypersynchronous and attain maximum current strength in middle or landward reaches, whereas for the barrier enclosed estuaries the maximum current strength occurs at the narrow tidal inlet.

In many estuaries, there exists an essentially closed circulation system for fine suspended particles, which causes them to become entrapped. This occurs due to the formation of "turbidity maxima" and from the "settling lag" effect. In the latter process, there is a time lag between the turn of the tide (when current velocity is zero) and when the concentration of fine suspended particle concentrations become minimum. This settling lag is due to the time it takes for the fine material to settle through the water column after the reduction in flow velocities (and reduction in turbulence), and thus the particle is carried some distance beyond the point where it starts to sink. Thus for a flood tidal current near high water, a certain amount of fine sediment settles toward the landward areas. The lag effect can explain why in many estuarine tidal flats there is a much greater proportion of mud particles than in the adjoining open sea, and why moving landwards up the estuary the particle size gradually fines (Postma 1967).

A "turbidity maximum" of suspended sediment concentration often occurs in the upper reaches of many estuaries, particularly in the partially mixed types, where suspended sediment concentrations may reach 10 to 100 times greater than either seaward or further up the river, and may reach 1–10 g/L. This feature occurs in a wide variety of estuaries over the world, and occurs because fine particle settling is trapped in the null zone where river current converges with the landward estuarine flow near the bottom (Nichols and Biggs 1985).

The formation of highly concentrated fluid mud layers at the bottom may also be part of the sediment dynamics. Fluid mud is a highly concentrated sediment suspension

with a sediment concentration of between 10,000 and 300,000 mg/L, and can originate from the turbidity maximum at slack water. It may take the form of mobile or stationary suspensions (Kirby 1988). But fluid mud can also form from wave action (Healy et al. 1999).

A typical feature of shallow estuaries is the estuarine "turbid fringe." This is generated by the wave action as the tide rises over the intertidal flats and reagitates the fine particles into suspension. Thus even in days of very light wave action a zone of brown turbid waters is observed around the shore of the estuary. Fine sediment transport in the estuary is also affected by specific processes such as aggregation of the fine particles, deposition, erosion, and consolidation. Classically, the aggregation of fine sediment particles was explained by the so-called electric double-layer theory. In recent decades, additional mechanisms have been identified including organic aggregation, bioflocculation, and pelletization.

biogeochemical cycling of elements. They therefore can strongly influence the environmental quality of coastal waters. Estuaries also protect coastal watershed areas, buffering infrastructure from the damaging effects of storms, floods, waves, and erosion. Because more than four billion people live within 60 km of the world's coastlines (Kennish et al. 2008), many inhabiting estuarine watersheds, these buffering effects are extremely important for sustaining coastal communities.

Various industries, aside from fisheries, depend heavily on estuaries for their successful operation. Most notable in this regard are aquaculture, electric power generation, oil and gas recovery, marine biotechnology, tourism, transportation, and shipping. Together, these industries inject trillions of dollars into the world economy each year. They also employ millions of people.

Estuaries: Anthropogenic Impacts

Michael J. Kennish

Department of Marine and Coastal Sciences, School of Environmental and Biological Sciences, Rutgers University, New Brunswick, NJ, USA

Definition

Anthropogenic impacts are defined as marked adverse effects of human activities on estuarine environments (Kennish 2015a).

Introduction

Estuaries are coastal environments with exceptional ecological, recreational, and commercial value (Day et al. 2012; Kennish 2015a). They provide a wide array of ecosystem services, including diverse habitats (e.g., open waters, submerged aquatic vegetation, unvegetated bottom sediments, tidal flats and creeks, and fringing wetlands) that serve as nursery, feeding, and refuge areas for numerous estuarine, marine, and terrestrial organisms. The rich food supply in estuaries supports many biotic communities. Numerous marine species of recreational and commercial importance utilize estuaries during their life; for example, these coastal systems play a significant role in the production of marine fisheries. Adjoining wetland habitats are particularly important in the life history of fish, shellfish, migratory birds, and other wildlife.

Within the land-river-coastal shelf continuum, estuaries serve a number of vital functions, including the filtering of contaminants, transformation of nutrients, and

Anthropogenic Impacts

Kennish (1992, 1997, 2002, 2005, 2015b) and Kennish et al. (2008) have examined the effects of human activity on estuaries. They have identified a wide array of anthropogenic stressors on these ecosystems which can be organized into 12 major categories. These include: (1) habitat loss and alteration; (2) enrichment (nutrients, organic carbon, and thermal loading); (3) sewage and pathogenic inputs; (4) chemical contaminants; (5) human-induced sediment/particulate inputs; (6) dredging and dredged-material disposal; (7) human-altered hydrological regimes; (8) invasive/introduced species; (9) overfishing; (10) climate change effects; (11) coastal subsidence; and (12) floatables/debris.

Habitat Loss and Alteration

Estuaries are particularly susceptible to habitat loss and alteration caused by human activities. Examples are physical changes in bayshore areas linked to the construction of lagoons, bulkheads, retaining walls, docks, piers, boat ramps, marinas, houses, roadways, and other infrastructure. Waterfront development which creates permanent structures, and excessive recreational and commercial use which alters bottom habitat especially in shallow waters due to boat engine prop scarring of seagrass beds and shellfish dredging of bay bottoms, have had profound consequences. Conservation zones have been established in some of the more sensitive and valuable estuarine habitat impacted by human activity. Dredging of lagoons, channels, and other estuarine areas disrupt benthic habitats for months or even years. Dredged-material disposal at selected sites in estuarine basins causes longer term alteration of habitat, albeit in restricted areas. Revetments constructed for bank stabilization along shorelines to mitigate erosion from coastal storms and currents and to protect against sea-level rise and inundation are increasing

in many regions. Other protective features are being installed or reconstructed in hazard zones, including storm walls, flood walls, and jetties. The damaging effects of major storms such as Superstorm Sandy in the mid-Atlantic region and Hurricane Katrina in the Gulf of Mexico have led to the application of innovative marine engineering strategies to increase the sustainability and resilience of coastal communities, land areas, and estuarine ecosystems.

Wetland habitat destruction has declined appreciably in the USA over the past 50 years as a result of strong regulatory controls, habitat restoration, and education programs. However, the loss of wetlands has continued unabated in other countries, particularly undeveloped ones. The losses have been acute in some countries. For example, most wetland and mudflat habitats along the mainland coast of the Dutch Wadden Sea have been lost due to reclamation, diking, levee construction, and conversion to polders. Parallel grid ditching, canal and levee construction, impoundment dikes, and open marsh water management (OMWM) have physically altered many salt marsh systems along the Atlantic and Gulf Coasts of the USA, their hydrological regimes, and biotic structure (Kennish 2001a, 2001b; Rochlin et al. 2012; Gedan 2015). Tidal flooding and drainage have been modified in many salt marshes, often reducing sediment input to the marsh surface and decreasing vertical accretion which could hasten submergence of these systems in response to climate-change driven sea-level rise.

In the USA, ~50% of the original salt marsh habitat was destroyed before 1970 (Kennish 1997, 2001b). Adam (2002) noted that considerable salt marsh area in Northern Europe has been altered as a result of land reclamation, pollution, tidal barriers, salt production operations, insect control, and introduced species. Burd (1992) indicated that 10–44% of the salt marshes in South East England were destroyed between 1973 and 1985/1988. The substantial losses of salt marshes along the lower Mississippi River have been attributed in large part to land subsidence together with a reduction in sediment load in the river due to dam construction upstream as well as extensive levee systems that preclude nutrient and sediment inputs to the marsh surface (Day et al. 2012; Mitsch and Gosselink 2015). Kennish (2001b) and Adam (2002, 2015) have provided a detailed account of the natural and anthropogenic stressors impacting salt marsh systems.

Similar losses have been reported for mangrove forests. For example, human activities have accounted for more than 50% of the mangrove forests lost in Southeast Asia and 75% of the mangrove forests lost in Puerto Rico (Alongi 1998; Kennish 2015b). Mariculture and silviculture operations are responsible for much of these losses. Mariculture ponds have replaced nearly 50% of the mangroves in the Philippines (Hopkins et al. 1995; Kennish et al. 2008).

Aside from bayshore construction and shoreline habitat modification, development of coastal watersheds has

converted extensive natural habitat to compacted soils and impervious cover that decrease infiltration of rainwater while increasing runoff, erosion, and nonpoint pollution to estuarine water bodies. Land use and land cover changes in these developed areas often translate into higher nutrient and sediment loads that often affect water and sediment quality of estuaries. A watershed impact threshold is exceeded when the amount of impervious surface cover is greater than 10% (Arnold and Gibbons 1996), and increasing water quality degradation of influent systems in coastal watersheds occurs with progressively greater impervious cover. Sprawl development accelerates the fragmentation of natural habitats in watersheds, creating an impediment to colonization and migration of wildlife. Freshwater diversions, dam construction, and impoundments alter hydrological and salinity regimes in influent systems and contiguous estuarine waters, affecting the structure and function of biotic communities. The channelization of streams and rivers for flood control enhances freshwater discharges to estuaries. However, dams reduce the downstream flow as well as inputs of sediments and other particulates. The diversion of freshwater for agriculture, municipal, and industrial uses also reduces freshwater inputs. This is exemplified by conditions surrounding San Francisco Bay, where more than 50% of the freshwater inflow is diverted elsewhere, mainly for agriculture use (e.g., irrigation) which accounts for more than 80% of the diverted water volume (Kennish 1997, 2004). Mining and silviculture usually raise sediment loads to estuaries, as well as metals and other contaminants transported to the coastal zone. These human activities have been problematic in many developing countries.

Enrichment

Enrichment, as used here, refers to the input of excessive amounts of nutrients, organic carbon, and heat (i.e., calefaction or thermal loading from electric power plants) to estuarine and coastal marine systems leading to ecological impacts. Nutrient enrichment, primarily nitrogen and phosphorus inputs from point and nonpoint sources, promotes algal blooms in estuaries and can cause anoxic and hypoxic conditions detrimental to biotic communities and habitats (Kennish 2002; Diaz 2015). The eutrophication of estuarine waters often has devastating consequences, at times culminating in heavy mortality of benthic and nektonic organisms, including recreationally and commercially important forms, and causing significant changes in estuarine community structure and function. Phytoplankton and macroalgal blooms (including toxic and nuisance algal blooms) stimulated by nutrient enrichment decrease light transmission to the benthos, and the shading effect typically reduces the production and areal distribution of seagrass and other favored habitats. The habitat change commonly results in a shift from seagrass-dominated systems to phytoplankton-

dominated systems in shallow coastal bays and lagoons (Kennish and Paerl 2010).

Nixon (1995) defined eutrophication as the increase in rate of production and accumulation of organic carbon in a system. The consequences of eutrophication in an estuarine waterbody are numerous and varied and include such impacts as low dissolved oxygen, harmful algal blooms (HABs), loss of essential habitat (e.g., seagrass and shellfish beds), lower biodiversity, reduced harvestable fisheries, imbalanced trophic food webs, declining system stability and resilience, diminished ecosystem services, and impacted human use. The effect of escalating eutrophication is potentially permanent alteration or loss of biotic communities and habitats and great ecosystem-level degradation (Kennish and de Jonge 2011). Influxes of nutrients from farmlands, animal feedlots, stormwater runoff, industrial wastewater discharges, sewage inputs, groundwater seepage, atmospheric deposition, and other sources have contributed to nutrient loading concerns in many estuaries. Increasing population growth and development in coastal watersheds have accelerated reactive nitrogen inputs to estuaries and the occurrence of estuarine eutrophication (Howarth 2008; Anderson et al. 2010).

Waste heat discharged by electric generating stations sited in the coastal zone has caused the calefaction of estuarine waters, affecting the physiological and behavioral responses of organisms most acutely in near-field regions of station outfalls (Kennish 1992, 1997). Biotic impacts often observed in these receiving waters are decreased primary production, altered reproduction, decreased growth, and increased mortality (e.g., heat-shock and cold-shock mortality of fish). Behavioral modification may be dramatic, with many nektonic organisms exhibiting avoidance or attraction responses to the heated effluent. Significant change in species composition, abundance, and diversity of biotic communities commonly occur in discharge canals of electric generating stations. Other more serious impacts of electric generating stations are the impingement and entrainment mortality of estuarine organisms, which usually far exceed the adverse effects of waste heat discharges.

Sewage and Pathogenic Inputs

Inputs of sewage and other organic wastes can exacerbate estuarine eutrophication problems by delivering excess nutrients and organic carbon to estuaries. These wastes may enter estuarine systems via malfunctioning septic systems, stormwater, domestic wastewater discharges, industrial effluents, farmlands, mariculture, wildlife, livestock and fish processing operations, dredged materials, marinas, and other sources. Organic carbon inputs from external sources augment the organic carbon pool generated within estuarine systems, including vascular plant subsystems (seagrasses, salt marshes, and mangroves), macroalgae, animal remains, and biodeposits (feces and pseudofeces).

Organic carbon levels are frequently highest (>100 mg/l) in estuaries receiving the largest volumes of sewage wastes. Overenrichment of sewage wastes in estuaries is linked to elevated biochemical oxygen demand and reduced dissolved oxygen levels. Hypoxia and anoxia of estuarine and shallow coastal marine environments have increased worldwide over the past 50 years largely due to anthropogenic activities (Diaz and Rosenberg 2008; Diaz 2015). Chronic organic carbon enrichment degrades benthic habitats and communities, altering species diversity, dominance, and density, while favoring proliferation of opportunistic forms (Diaz and Rosenberg 1995).

Pathogens (bacteria, viruses, protozoans, and helminths) increase in estuaries receiving sewage wastes. In these polluted waters, they pose a health risk to swimmers and humans consuming contaminated shellfish. Consumption of raw, viral-tainted shellfish can cause hepatitis and serious gastroenteritis. Pathogenic bacteria in estuaries are particularly threatening to human health. For example, *Vibrio cholerae* causes cholera-like infection (diarrhea, dehydration, and vomiting), and other pathogenic bacteria (*Shigella* spp. and *Salmonella typhi*) are responsible for dysentery and typhoid. *Escherichia coli* causes gastroenteritis and other maladies. Indicator bacteria (enterococci, fecal streptococci, and total coliform bacteria) have been used in monitoring water quality at bathing beaches and in shellfish growing waters to reduce health risks to humans. Helminths and protozoa in estuaries also raise potential health concerns. Among problematic helminths are hookworms, roundworms, tapeworms, and whipworms that are commonly associated with untreated sewage and sludge. *Entamoeba histolytica*, a pathogenic enteric protozoan that can impact human health, is also transmitted via raw sewage contamination (Kennish 2004). Aggressive management programs have been instituted in many coastal communities to better control pathogenic contamination of estuarine waters, including identifying and restoring function of malfunctioning septic tanks and sewage treatment facilities, replacing combined sewer overflows, as well as improving agricultural and livestock management, stormwater runoff, and boat and marina sanitary protocols.

Chemical Contaminants

Bottom sediments of estuarine and coastal marine environments are repositories for chemical contaminants, particularly near heavily populated metropolitan centers and other urbanized areas. Examples are the bottom sediments of Boston Harbor, Newark Bay, Raritan Bay, upper Chesapeake Bay, and San Francisco Bay (USA). However, even in suburbia, where land development and industrial activity have increased during the past several decades, contaminant input to estuaries can be significant. Bottom sediments accumulate chemical contaminants because many of the contaminants are particle reactive, sorbing to grain surfaces, and settling to the

estuarine floor. Some chemical contaminants concentrate in estuarine organisms or in the water column. In coastal watersheds, both point and nonpoint sources of chemical contaminants may occur, although nonpoint sources have become increasingly more important through time because of greater effectiveness in controlling the point source inputs to receiving waters. Principal delivery systems to estuaries include urban and agricultural runoff, municipal and industrial discharges, groundwater inputs, river inflow, and atmospheric deposition (Kennish 2015b). Some polluting substances enter estuaries from the weathering and erosion of rocks, soils, and ore-bearing deposits as well as from volcanic activity and atmospheric deposition.

Metals, halogenated hydrocarbons, and polycyclic aromatic hydrocarbons are major groups of chemical contaminants found in estuaries (Kennish 1992, 1997). When present in elevated concentrations, they are potentially damaging to estuarine organisms and habitats. Oil spills from vessels have severely impacted some estuaries, with the released aromatic and aliphatic hydrocarbons causing impairment of vital habitats (e.g., estuarine floor and beaches, mudflats, and salt marshes) and biotic communities for decades. Oil entering estuaries in wastewater discharges from coastal watersheds and fixed installations has also been detrimental. Volatile organic compounds (VOCs), while less threatening over the long term, can be acutely toxic as well.

Metals pose a potential danger to estuarine organisms because of their acute or chronic toxicity at higher concentrations, tendency to bioaccumulate, and persistence in the environment. Metals of concern include the transition metals (e.g., copper, cobalt, iron, and manganese), metalloids (e.g., arsenic, cadmium, lead, mercury, selenium, and tin), and organometals (e.g., methylmercury, tributyltin, and alkylated lead) (Kennish 1997, 1998; Kennish et al. 2008). Important anthropogenic sources of metals to aquatic systems are smelting facilities, tanneries, solid waste dumpsites, municipal wastewater systems, fossil-fuel combustion, dredged spoils, refineries, electroplating, and dye manufacturing. The uptake of metals by estuarine and marine organisms occurs via the removal of the contaminants from solution, from bottom sediments or interstitial waters, and from ingestion of food and suspended particulates. Some of these organisms have the capacity to internally regulate the concentrations of metals through activity of metallothioneins and lysosomes, which play a significant role in the sequestration and detoxification of the contaminants. Metals are potentially toxic to estuarine organisms above a threshold bioavailability; exposure of the organisms to elevated concentrations of metals may lead to a range of physiological and pathological responses, such as growth inhibition, aberrant reproduction and development, tissue degeneration, neoplasm formation, and genetic derangement. Other processes that can be adversely affected are respiratory metabolism, feeding, and

digestive efficiency which, when seriously impaired, cause an increase in mortality. Abundance and distribution of these organisms are often altered in the estuary as well. The effects are manifested most conspicuously in benthic communities that inhabit sediments with high metal burdens.

Halogenated hydrocarbons are some of the most persistent, ubiquitous, and chronically toxic contaminants found in estuaries. They mainly originate from agricultural and industrial sources and include an array of biocides (e.g., insecticides, herbicides, and fungicides), low-molecular-weight compounds (e.g., chlorofluorocarbons), and high-molecular-weight chemicals (e.g., chlorinated aromatics and chlorinated paraffins). Some of the most notable synthetic organic compounds belonging to this group of contaminants (e.g., PCBs, DDT, and non-DDT pesticides) rank among the most toxic constituents in estuaries (Kennish 2004). They are suspected etiologic agents which have been linked to a number of disorders in estuarine animals such as reproductive abnormalities, altered endocrine physiology, aberrant developmental patterns, skin and liver lesions, and cancer. DDT and PCBs are particularly hazardous substances because they biomagnify in food chains (Kennish 1997). Therefore, they pose a potentially serious threat to humans who consume contaminated seafood products.

Polycyclic aromatic hydrocarbons (PAHs) are also widely distributed contaminants, being found in estuarine environments worldwide. They largely derive from fossil fuel combustion, land runoff, municipal and industrial wastewater discharges, and oil spills (Kennish 1992). Natural processes (e.g., volcanic activity) also generate PAHs, but their inputs to estuaries are low relative to human sources. PAHs are a problematic class of contaminants because the higher-molecular-weight forms are predominantly carcinogenic, mutagenic, and teratogenic, and the lower-molecular-weight forms can be acutely toxic (Kennish 2004). PAHs, when readily bioavailable, produce hepatic neoplasms (e.g., hepatocellular carcinoma, hepatocellular adenoma, and cholangiocellular carcinoma) and other disorders in demersal fish and shellfish (Kennish 1997). They are also responsible for a range of sublethal effects manifested as biochemical, behavioral, physiological, and pathological aberrations in organisms that can contribute to changes in the structure of estuarine communities.

Human-Induced Sediment/Particulate Inputs

Land use and land cover changes in coastal watersheds coupled to development of shore communities facilitate sediment and other particulate inputs to estuaries, contributing to biotic and habitat impacts. The removal of natural vegetation and soils during construction of buildings and other structures promotes erosion and delivery of sediments to streams, rivers, and estuaries. Even more dramatic is the loss of large volumes of sediment to aquatic systems via deforestation associated

with silviculture operations. Sediment delivery to estuaries via these processes typically increases water column turbidity, light attenuation, and shading of the estuarine floor, thereby decreasing production of seagrass beds and other benthic habitat that supports numerous faunal populations including many commercially and recreationally important finfish and shellfish species. Moore et al. (2012, 2014) showed that elevated turbidity in some areas of the Chesapeake Bay system is responsible for the loss of extensive seagrass beds which once supported benthic communities. The degradation of these biotopes can significantly reduce production of an estuarine system.

Dredging and Dredged-Material Disposal

There are both direct and indirect impacts of dredging and dredged-material disposal in estuaries. The most profound direct impacts relate to the removal of bottom sediments and destruction of the benthic habitat and communities. The dredging action causes mechanical injury and smothering of organisms entrained in the sediments extracted from the bottom, typically causing mass mortality. Successful recruitment and recolonization of the dredged site by benthic organisms may not occur for a year or more. The disposal of dredged material at restricted locations results in similar impacts on the benthos (Kennish 1997, 2015a).

Dredging increases turbidity levels substantially in an estuary, although these effects are ephemeral. Elevated turbidity reduces light penetration in the water column which can adversely affect the growth and production of phytoplankton and submerged aquatic vegetation. The roiling of sediments at the dredged site also releases nutrients and chemical contaminants from the bottom sediments, remobilizing them to other areas of the system. Thus, water quality can be adversely affected as well.

On the positive side, dredging increases circulation in an estuary. Deepening of channels promotes recreational and commercial usage of the system. Sediment removed by dredging is often used for beach and bayshore nourishment to mitigate erosion effects and enhance land habitats.

Human-Altered Hydrological Regimes

Both natural and anthropogenic factors affect freshwater inflow to estuaries that modulates their physical-chemical and ecological characteristics. Freshwater inflow to estuaries varies seasonally and annually with the flux of precipitation, catastrophic storms, and major flooding events. Local and regional drought conditions – stochastic natural disturbances – often cause substantial reduction in surface and groundwater inflow that decreases estuarine flushing and increases water residence time and salinity. During other periods of increased precipitation, opposite conditions occur, with greater estuarine flushing and reduced water residence time and salinity. The vagaries in these natural drivers of change are exacerbated by anthropogenic

factors. For example, coastal watersheds that are heavily developed with impervious cover exceeding 10% have greater surface runoff to rivers, estuaries, and the coastal ocean than less developed coastal watersheds. Other system modifications, such as channelization and the loss of salt marshes and other wetlands, increase freshwater flows to estuaries which concomitantly increase inputs of nutrients and chemical contaminants commonly stored in soils and deeper sediments. In contrast, freshwater diversions in coastal watersheds for agricultural, municipal, and industrial needs decrease freshwater inputs to estuaries, as do dams and reservoirs in upland drainage basins. The effects of the reduced freshwater inflow are compounded during dry years. Excessive groundwater pumping for farmland irrigation and domestic uses has resulted in saltwater intrusion in some regions. Flood control structures installed to mitigate storm surge caused by hurricanes and major coastal storms also affect water-flow regimes in estuaries. With the increase in sea-level rise driven by climate change, there is growing awareness and concern about the effects of installing these structural features to mollify flooding and other bayshore impacts (Kennish 2002, 2015a; Kennish et al. 2008).

Changes in the circulation and salinity regimes of an estuary due to natural and anthropogenic fluxes in freshwater inputs can significantly affect the structure and function of biotic communities. The species composition, abundance, and distribution of floral and faunal communities will change with shifts in the estuarine salinity gradient. Changes in freshwater inflow will also alter an estuary's capacity to dilute, transform, and flush contaminants accumulating in the system (Kennish 2004, 2015a).

Introduced/Invasive Species

Introduced and invasive species have altered biotic communities in estuaries worldwide. These nonnative species often adapt very successfully to their new environments, outcompeting and excluding many native species and disrupting the trophic organization. In some cases, the ecological balance of the system is altered by acute reduction in biodiversity and increase in dominance by the nonnative forms. The adapted habitats of the introduced and invasive species commonly lack natural controls, enabling these forms to rapidly dominate the native plant and animal communities and potentially impacting the ecological and economic components of the system. New pathogens and parasites may enter estuarine water bodies with these nonnative species, leading to the spread of infectious diseases and harmful parasites. Recreational and commercial fisheries can be adversely affected as well, as can wetlands and other habitats (Kennish 2005, 2015b).

Many nonnative species have been deliberately introduced into estuaries for recreational or commercial purposes, an example being the introduction of the striped bass (*Morone saxatilis*) to San Francisco Bay (USA). In fact, San Francisco Bay is one of the most heavily “invaded” estuaries in the

world, with nearly 250 species of plants and animals being nonindigenous (Cohen and Carlton 1998). More than half of the fish species in the delta region consist of exotic, nonnative forms, and most macroinvertebrates along the inner, shallow water habitats of the bay are introduced species (Kennish 2000). Among the prominent introduced species in this estuary are the smooth cordgrass (*Spartina alterniflora*), oyster drill (*Urosalpinx cinerea*), and striped bass (*M. saxatilis*). The Asian clam (*Potamocorbula amurensis*), an introduced bivalve that has outcompeted native clam species (e.g., *Macoma balthica* and *Mya arenaria*), has seriously decimated the phytoplankton community of Suisun Bay. Dramatic changes in the native biotic communities of San Francisco Bay have been well chronicled (Kennish 2000, 2004).

The number of introduced and invasive species is on the increase in estuaries for several reasons. First, many species are expanding their geographic range as the planet warms in response to climate change, enabling the species to extend their distribution to higher latitude regions and estuarine water bodies previously uninhabitable for them. In addition, greater marine shipping and transportation provides an avenue for global transport of potential invasive species. Furthermore, more mariculture and other estuarine and coastal marine commercial ventures enable additional nonindigenous species to adapt to new estuarine environments.

Overfishing

The escalating human population, particularly in the coastal zone, is placing greater pressure on fisheries resources in estuarine and marine waters. The societal demand for seafood has led to the overexploitation of many recreationally and commercially important finfish and shellfish species and the collapse of some of them. Excessive fishing pressure on some species has been allayed by the expansion of aquaculture in many countries. Government regulations have been formulated as well to protect viable fisheries.

Overfishing not only depletes finfish and shellfish stocks but also impacts the structure and function of biotic communities. For example, the collapse of a major piscivorous fish population often results in the rapid increase of its prey species and potential imbalances in community structure and altered ecosystem function (Pinnegar et al. 2000; Kennish 2005). The fishing pressure on many marine species is unsustainable (Pauly et al. 1998). The trend therefore has been to “fish down” marine food chains, rendering affected ecosystems impoverished and less valuable (Williams 1998). The global catch has shifted from large piscivorous species to smaller planktivorous forms (Boehlert 1996). Since many recreationally and commercially important marine finfish species utilize estuaries at some point during their life history, estuaries are critically important to the long-term viability of these species.

Climate Change Effects

Climate change is rapidly becoming one of the most serious environmental, economic, and societal concerns around the world. The effects of climate change are multifaceted, impinging on agriculture, manufacturing, energy systems, fisheries, transportation, shipping, tourism, emerging technologies, and other major sectors of developing and developed nations. The earth is warming, and the consensus among climate scientists is that anthropogenic activities account for much of it (Oreskes 2004; Anderegg et al. 2009; IPCC 2013). Increasing global temperatures, ascribed in large part to carbon dioxide emissions, have been linked to greater frequency and severity of damaging storms, ongoing sea-level rise, coastal flooding, droughts and fires, and other hazards projected by climate forecasting models for the twenty-first century (IPCC 2013). Carbon dioxide levels in the atmosphere now exceed 400 ppm, the highest in centuries. Extreme climate events and sea-level rise will be increasingly hazardous to coastal communities worldwide. The damaging effects of major storms such as Superstorm Sandy in the Mid-Atlantic region (USA) and Hurricane Katrina in the Gulf of Mexico (USA) have drawn much attention to the seriousness of these phenomena.

Eustatic sea-level rise is attributed to thermal expansion of the oceans and the melting of mountain glaciers and continental ice sheets. During the twentieth century, the mean global temperature increase was 0.8 °C (1.4 °F), being responsible for <50% of the average eustatic sea-level rise of 1.8 ± 0.3 mm/yr. Global sea-level rise is currently 3.3 ± 0.3 mm/yr. The rate of sea-level rise will continue to increase during the twenty-first century, as demonstrated by climate change models, with the total sea-level rise expected to range from 52–98 cm (IPCC 2013).

Relative sea-level rise, however, is much greater in some regions, such as the Mid-Atlantic region of the USA. As noted by Milne et al., (Milne et al. 2009) and Miller et al. (2013), relative sea-level rise is affected by several important elements: (1) global average sea level; (2) regional and local subsidence or uplift (including thermal subsidence, sediment loading, flexural, and glacio-isostatic adjustment effects), gravitational, rotational, and flexural effects due to changing ice sheets; and (3) oceanographic effects (dynamic topography and tide-range change effects). Hence, during the twentieth century, the relative sea-level rise in the Mid-Atlantic region (USA) was nearly twice that of the global sea-level rise.

During the twenty-first century, climate change effects will significantly impact low lying coastal areas, including estuaries. However, because of the multiple environmental stresses from a wide range of local and regional anthropogenic activities, identifying the climate change impacts on estuaries could be complicated (Cronin 2015). Despite this complexity, climate models indicate that the frequency of coastal storms and storm surge will increase along with precipitation,

accelerating estuarine shoreline erosion and flooding of bayshore areas. Rising sea level and coastal inundation will also lead to substantial loss of some coastal wetlands, converting them to open water habitat, eliminating their protective buffer, and leaving coastal communities more vulnerable to extreme weather events (Kennish et al. 2008). While some wetland systems will be able to migrate inland with rising sea level, others will be subject to coastal squeeze due to human development behind them, causing the habitat to be submerged by the encroaching sea. For example, ~30% of the coastal salt marshes in New Jersey (USA) cannot migrate inland because of development.

Human-induced climate change will alter freshwater inputs, temperature and salinity regimes, biogeochemical processes, and the structure and function of biotic communities in estuaries (Kennish 2002, 2015a). Higher temperatures will result in latitudinal shifts in the distribution of many estuarine plant and animal species, and the migration patterns of others will be significantly altered. Estuarine basins will be modified, widening and deepening in response to sea-level rise. Shifts will occur in nutrient and sediment supply as well as freshwater inflow. In addition, tidal prisms and tidal ranges will change in many systems, altering basin circulation. The upstream penetration of saltwater will destroy extensive plant and forest vegetation in coastal watersheds and cause saltwater intrusion of potable water supplies. The ecological landscape of lower watershed areas will change considerably. Carefully crafted mitigation and adaptation plans will be needed for coastal communities to effectively deal with these coastal zone changes.

Coastal Subsidence

Human activities are contributing substantially to coastal subsidence in some areas; they often exceed the effects of natural processes. For example, oil and gas extraction (e.g., Galveston, Texas, USA) and groundwater withdrawal (e.g., Atlantic City, New Jersey, USA) have exacerbated the effects of eustatic sea-level rise by increasing relative sea-level rise and leading to the submergence and loss of estuarine and wetland habitats. Natural processes – compaction of subsurface sediments, tectonic (crustal) movements, and sinkhole formation – augment these effects. In coastal areas of the Mid-Atlantic region, relative sea-level rise effects are significant, with the subsidence of thick Cretaceous to Holocene unconsolidated sands, silts, clays, and gravels being driven by thermoflexural (the combination of thermal subsidence and sediment loading offshore, producing flexural subsidence onshore) and compaction effects (Kominz et al. 2008; Miller et al. 2013); Boon et al. (2010) reported subsidence rates of –1.3 to –4.0 mm/year at Chesapeake Bay. Acute subsidence is also evident along the northern Gulf of Mexico (i.e., Louisiana coast) where sediment compaction and downwarping of the underlying crust contribute greatly to rapid coastline

retreat. Biotic effects of coastal subsidence in estuarine environments are often most evident in fringing wetland habitats.

Floatables/Debris

Estuaries are environments which accumulate large amounts of floatables and other debris because of their close proximity to coastal communities and the heavy recreational and commercial utilization (Kennish 2001a). This is a worldwide problem. Litter is discarded from boats or shoreline areas, and much debris also enters estuaries via stormwater discharges and river inflow. Plastics are particularly detrimental because they can damage power plant intake systems and other engineered infrastructure, seriously foul habitats, and pose a hazard to estuarine organisms. Fish, birds, turtles, and marine mammals can be injured or killed when entangled in fishing line, nets, packing bands, and other synthetic debris. Plastics, when ingested, commonly obstruct the digestive systems or air passages of these animals, causing their death. Furthermore, the plastics are not biodegradable and can remain entrapped in estuaries for many years, threatening biotic communities indefinitely. Because the use of plastics has increased dramatically over the past several decades (Kennish 2001a), they have created serious pollution problems in estuarine and coastal marine environments (Ribic 1998; Kennish 2015b).

Conclusions

Estuaries are affected by many anthropogenic factors that can compromise the structure and function of biotic communities, the integrity of habitats, and the condition of entire ecosystems. Twelve major categories of anthropogenic stressors have been identified in estuaries. These include: (1) habitat loss and alteration; (2) enrichment (nutrients, organic carbon, and thermal loading); (3) sewage and pathogenic inputs; (4) chemical contaminants; (5) human-induced sediment/particulate inputs; (6) dredging and dredged-material disposal; (7) human-altered hydrological regimes; (8) invasive/introduced species; (9) overfishing; (10) climate change effects; (11) coastal subsidence; and (12) floatables/debris. Anthropogenic impacts on estuaries are increasing because of ongoing human population growth and development in coastal watersheds and the heavy recreational and commercial use of these coastal systems. In addition, interactions between two or more anthropogenic stressors can be synergistic, creating more serious impacts together than when acting alone.

Estuaries are sites of intense human activity, and thus sound management strategies must be formulated to protect them. Best management practices are required to minimize anthropogenic impacts, and education programs must be developed to inform the public of their stewardship responsibilities to protect and improve estuarine systems. There also

needs to be a strong outreach initiative to interpret scientific findings and connect with coastal communities on the condition and health of estuarine environments. Finally, effective restoration projects must be instituted to revitalize degraded habitat and improve biotic communities.

Europe, Coastal Ecology

J. Pat Doody

National Coastal Consultants, Brampton, Huntingdon, UK

Introduction

Europe occupies a little less than 7% of the total area of the world land surface. For its size its coastline is long, estimated at 143,000 km (Stanners and Bourdeau 1995). The European figure is derived from a map of 1:3 million scale and represents a conservative figure. The coastlines of Great Britain and Greece, for example, are 18,838 and 15,000 km, respectively, when the many islands are included. Though the figure for Great Britain is taken from measurements made at a scale of 1:50,000 and not directly comparable with the European figure they give an indication of the scale of the resource.

Europe's landmass is bounded by the Atlantic Ocean in the west and includes several enclosed seas (Fig. 1). The basic fabric of the coast is formed from rocks which span the whole of the geological timescale from the Precambrian period (3,000–570 million years ago) to the rocks laid down in the Cretaceous–Tertiary period (140–2 million years ago). Superimposed on this structure, in the north, is the effect of the ice-ages of the Quaternary period (2 million to 10,000 years ago) and the glacial deposits, which were left behind as the ice melted. In the south, tectonic activity associated with volcanoes and earthquakes has also had an impact, though on a more limited geographical scale.

A combination of oceanographic factors (such as tides and sea-level change) as well as climatic effects, force the landward or seaward movement of sediments derived from erosion of the land or seabed. This provides opportunities for

new coastal areas to develop as the material is deposited on or adjacent to the land. A variety of other variables, including the ameliorating effect of the warm Atlantic waters and westerly winds help to define a west to east climatic gradient, which is most clearly seen in the nature of the vegetation. Human activities have also been important, though more recent in their impact, causing modification or loss of habitat and “squeezing” the coastal zone (Doody 2001a). The description that follows provides an overview of the nature of Europe's coastline from Norway to the eastern Mediterranean and the flora and fauna which occur there.

The “Nature” of Europe's Coast

The coastline and marine waters of Europe are areas of great contrast with a high diversity of wildlife and landscape features. The underlying geology helps to define the coast and its landscape. Today, in many areas where the coastline is composed of “hard” rocks resistant to erosion, it may appear unchanging. However, during the 2 million years or so of the Quaternary Period the growth (and retreat) of the ice sheets eroded mountains and scoured river valleys. In the north and west from Norway to the Atlantic coasts of Ireland and western Britain, the combined effects helped to mold the landscape, exposing some underlying structures and covering others. This glaciated northern landscape exists today as a highly indented coast with exposed sea cliffs, coastal inlets (including fjords, fjards and firths, and a few, usually small estuaries), rocky shores, and pocket beaches. By contrast, the coasts of southern England, France, northern Spain, and Portugal include “softer” though resistant limestone molded by more recent events (such as erosion from the sea and land slip) to form cliffs and headlands. Hard igneous rocks of Precambrian age and resistant granites also abound in the northern Baltic. Here, the lie of the land is gentler and cliffs are much less evident. Isostatic rebound continues to create small flat offshore islands. At the southern limits of the ice sheets, in the southern North Sea and the Baltic Sea particularly (Fig. 1), major deposits of glacial sediment left behind as the ice retreated northwards have helped to create the present low-lying landscapes. These provided abundant soft sediments for reworking during the Holocene epoch of the last 10,000 years. Today eroding glacial till cliffs, sand dunes, salt marshes and tidal sand, and mud flats are abundant. These combine to form large estuaries in the meso-to macro-tidal southern North Sea and deltas on the micro-tidal shores of the southern Baltic. Within the matrix of sandy spits and bars and tidal flats, promontories of harder limestone rocks help form embayments in a few locations. Sub-tidal areas also tend to be dominated by softer sediments on the sea bed.

The Mediterranean Sea has both hard and soft rocks, the former pre-dominating as karstic limestone cliffs, and more

Europe, Coastal Ecology,**Fig. 1** Europe's seas

gently sloping rocky shores. Generally, the land rises uninterrupted from the sea. Where cliffs occur these can reach a height of over 150 m, as on the southern coast of Spain. Over the last 4000 years or so erosion of the mountains has also helped to create large coastal plains as their river catchments have delivered sediment to the coast. In the micro-tidal areas of both the Mediterranean and Black Seas large deltaic systems such as the Ebro Delta in Spain, the Po Delta in Italy, and the Danube Delta in the Black Sea have grown partly in response to deforestation in the hinterland (Figs. 2 and 3).

Sea-Level Change, Tidal Range, and Wave Action

Long-term sea-level change is a major determining factor in the development of the coastline and coastal habitats. From around 7000 years ago, when sea level began to stabilize at its present level, many of the coastal formations that are present today began to develop. Their evolution then and now depends on a combination of factors, including the availability of sediment and the influence of sea-level change, tidal range, and wave action.

With global sea levels rising today at about 1–2 mm per year (Warrick 1993) there appears to be a general trend towards erosion and mobilization of sediments. Exceptions occur where isostatic rebound of glaciated areas is rising faster than sea level, causing a general rise in the land relative to the sea in areas such as Norway, the Gulf of Bothnia and around the margins of the Central Highlands of Scotland. Where the land continues to sink or is stable, relative sea-level rise tends to push coastal habitats toward the land. When this migration is restricted by resistant, rising landforms or artificial structures built to defend the land from erosion and/or flooding, the shore is squeezed into an ever narrower zone. This has important implications not only for the habitats themselves, but also the ability of the coastal landforms to

provide a flexible response to storms and extreme tidal events. It may also impact on human use and infrastructure at the coastal margin.

Tides and tidal range provide a further mechanism for change. Where large amounts of material are available for transport extensive sedimentary habitats can be created. In the macro-tidal areas (spring tidal range 4 m) of the west, including the Celtic Seas, the Bristol Channel (where the tidal range, at 12 m is the second highest in the world) and the Atlantic coast of France, sediments are moved inland to fill inlets and bays, creating estuaries. In meso-tidal (spring tidal range 2–4 m) or micro-tidal areas (spring tidal range 2 m) the tides have progressively less influence. At the lower end of the tidal range the sediment movement is offshore, with rivers tending to exert a more dominant role. Waves and wave energy help determine the final configuration of the deltas as in the Baltic and the Mediterranean.

Climate

The coasts and seas of Europe encompass a wide range of climatic conditions from the Arctic Circle to the deserts of north Africa. Summer temperatures rarely rise above 10 °C in most northern latitudes. This gradient is further influenced in the west by the marine waters, which are warmed by the Gulf Stream, creating an extreme maritime climate, which helps to define the Atlantic biogeographical zone encompassing much of northwest Europe (Polunin and Walters 1985).

Unlike the areas further north the climate of the Mediterranean is very different. The winters are warmer (averaging 6 °C) and the summers dry and hot. The range of temperature is much greater than on the Atlantic coast. The combination of thin limestone soils, dry climate and the long history of grazing and burning of the natural vegetation, has helped to create low-growing shrubby, drought and grazing resistant vegetation, which covers large areas of the Mediterranean.

Europe, Coastal Ecology,**Fig. 2** Distribution of the “cliffed” coastlines of Europe**Europe, Coastal Ecology,****Fig. 3** An elevated coastline (the Old Man of Hoy, Orkney Islands, Scotland)

Since storms and waves are generated over a smaller sea area than the Atlantic, extreme exposure to gales is less evident than on the Atlantic coast.

Elevated Landscapes: Sea Cliffs

Sea cliffs help to create some of the most spectacular and remote landscapes in Europe. They may have vertical or sloping faces, and in exposed locations are often drenched in salt spray, especially where they face the full extent of the Atlantic Ocean, and in the northern North Sea. Their orientation (and hence degree of exposure) and the nature of the underlying rock helps to determine the type of vegetation growing there. Although not considered in detail here stability is also an important factor helping to perpetuate shallow skeletal soils.

Sea Cliff Vegetation

Three main types of vegetation have been identified in the European Union Habitats and Species Directive, (European Commission 1999). A brief description of the first two is given below.

Vegetated sea cliffs of the Atlantic and Baltic coasts. In exposed areas with hard rock cliffs, some of the best examples of maritime cliff vegetation in Europe are to be found. These include communities dominated by roseroot *Sedum rosea* and Scot's lovage *Ligusticum scoticum*, on the salt-spray drenched cliffs. Above this spray zone, the cliffs support communities that include arctic-alpine plants including purple saxifrage *Saxifraga oppositifolia*, moss campion *Silene acaulis*, mountain avens *Dryas octopetala* and in Scotland the endemic Scottish primrose *Primula scotica*. In some areas, the extent of the truly maritime zone can be small. In sheltered locations, such as the east coasts of Ireland and Scotland, the cliffs are only marginally exposed to the full power of the wind, breaking waves and salt spray. Here, the maritime influence is reduced and plants less resilient to exposure and salt spray grow in communities more typical of inland locations. Further south from south west Ireland, Wales and south west England to southern Portugal, spectacular west facing cliffs also occur. These are less resistant than the harder rocks further north and in some areas rapid rates of erosion (1 m or more per year) can be measured as, for example, in the chalk cliffs of the Channel coast. Although still exposed to the Atlantic Ocean and its gales, climatic amelioration also allows a richer flora to develop. In limestone areas of south west Britain, northern France, and Spain the cliffs provide important refuges for warm loving species, such as spider orchid *Ophrys sphegodes*, formerly typically found in inland grasslands. In some areas, cliffs provide the most spectacular natural rock gardens, as at Cape St. Vincent in Portugal, where the endemic *Cistus palinhæ* is one of the many species present.

Vegetated sea cliffs of the Mediterranean coasts with endemic Limonium spp. Unlike the corresponding cliffs in the north and west, the incidence of exposure and hence the maritime nature of cliff vegetation in the Mediterranean is much reduced. Exceptions include the megacliffs of Croatia (Velebit) which represent a coastal habitat of exceptional biological importance. The habitats present range from emerging rocks with a calcifying algal community to sea water-drenched hyper-saline communities, including *Arthrocnemum glaucum* and *Atriplex portulacoides*, to exposed windswept cliff tops from 460 to 1200 m high. Interspersed in more sheltered areas are woodlands and scrub. There is little elsewhere in the literature concerning these habitats though reference is made to similar cliffs in Albania and southwest Turkey (van der Maarel 1993). These areas should probably be considered alongside the Atlantic woodlands of the northwest and the laurel forests of the Canary Islands for their conservation importance. The vegetation of all of these is to one degree or another dependent on its presence of moisture-laden air derived from strong onshore winds.

Sea Cliffs and Seabirds

Because of the close proximity to the rich waters of the Atlantic Ocean and the North Sea, coastal cliffs often support large colonies of nesting seabirds. The most common and conspicuous species are guillemot *Uria aalge*, kittiwake *Rissa tridactyla*, fulmar *Fulmarus glacialis* and razorbill *Alca torda*, which nest on ledges. Steep-sided granite cliffs may support large populations of gannet *Sula bassana*. On sloping cliffs where soil has accumulated, species which prefer to nest in burrows are found in high numbers such as puffin *Fratercula arctica* and manx shearwater *Puffinus puffinus*. Sea cliffs also provide nesting sites for a rare birds of prey such as the peregrine *Falco peregrinus* and the raven *Corvus corax*.

Seabird colonies do occur on cliffs and islands on more southerly coasts, though the populations, especially of cliff-nesting species are much smaller. Birds of prey are important and of these Eleonora's falcon *Falco eleonora* is of special significance. It is a small falcon feeding mostly on small birds. It migrates northwards from Madagascar where it is widely dispersed feeding on a range of insects and in a wide variety of habitats. These include coastal cliffs and cultivated areas, rice fields, lightly wooded slopes or coastal plains. It breeds in colonies on steep rocky coastal cliffs and islands, mainly in the Mediterranean. The breeding season is later than other species and timed to coincide with passerine migrations, ensuring a supply of food for its young.

"Soft" Rock Landscapes: Unconsolidated Cliffs

Cliffs derived from unconsolidated deposits of clay (including glacial material), loam or other easily eroded

sediments occur throughout the area. Landslip is common in sand and clays in the southern North Sea, southern Baltic Sea and on the south coast of England and in the sedimentary deposits of the Black Sea. Continuous erosion can result in the formation of high sloping unstable cliffs with little or no vegetation other than ephemeral communities. Where erosion is more episodic, the slopes can support scrub and even woodland on ledges remaining stable over periods of one hundred years or so. In these situations, some of the least “maritime” of the coastal cliff vegetation is found and may be indistinguishable from inland types.

The release of sediment during periods of erosion is an important factor in the development of coastal systems elsewhere. Preventing erosion in order to protect buildings or other human land uses can have consequences for habitats along the shore. As less sediment is available for movement by longshore drift opportunities for the creation of new beaches, themselves a form of coast protection, is restricted. In extreme cases adjacent habitats may be so deprived of sediment that they begin to erode.

Complex Sedimentary Systems

In contrast to cliffed landscapes, sedimentary landscapes are characteristically low-lying (Fig. 4). They can include a variety of very different habitats and are often highly unstable. Tidal flats and salt marshes, sand dunes, and gravel are the main formations that help to define the ecosystem. Coastal wetlands may include some or all of these habitats though the tidal habitats, especially sand and mud flats, have a special significance and are

described first. The short-to medium-term influence of tides and waves, freshwater inflows and sediment movement, or longer-term trends associated with sea-level change can result in the systems being very complex both spatially and temporally. Included within this section are the other components that make up the complex coastal sedimentary habitats, including the more terrestrial sand dunes and gravel structures.

Coastal Wetlands

Coastal wetlands occur throughout Europe (Fig. 5). Wolff (1989) estimates that intertidal areas cover 9300 km², excluding small wetland areas in Iceland, Russia, Norway, Spain, Portugal, and Italy where little or no information is available. This implies that intertidal wetlands cover only 0.09% of Europe’s land surface, a figure clearly highlighting the scarcity of the habitat type. They are most extensive in the major estuaries of the southern North Sea and the deltas of the southern Baltic and Mediterranean Seas. The Wadden Sea in Holland, for example, has approximately 123,900 ha and the Ebro Delta in Catalonia, one of the five biggest in the Mediterranean/Black Sea area has some 350,000 ha of tidal and former tidal land.

Estuaries. Estuaries, deltas, and lagoons lie within a range of coastal wetlands which have specific characteristics defined partly by the geographical location and degree of sediment input. In the north and west fjords and fjards, usually considered to be a special form of estuary, are specifically associated with glaciated areas and have limited inputs of sediment. The former are drowned glacial troughs, often associated with major lines of geological weakness. They have a close width–depth ratio, steep sides and an almost

Europe, Coastal Ecology,

Fig. 4 Low-lying sedimentary coastal plain derived from sediments eroded from the hills of northern Albania

Europe, Coastal Ecology,**Fig. 5** Distribution of coastal wetlands in Europe. (Adapted from Doody 2001b)

rectangular cross section. Sediment deposition is mostly restricted to the head of the fjord where the rivers usually discharge. The latter are glacial relicts on lowland coasts; ice-scoured rock basins, bars and small islands are characteristic features. Rias also have limited sediment and are formed when river valleys were inundated at the end of the last glacial period. They occur on the exposed western shores of Europe in macro- or meso-tidal areas. They are characteristically steep-sided with wooded slopes and occur in south west England and northern France, Spain, and Portugal.

Estuaries usually have major inputs of sediment. They are “partially enclosed bodies of water, open to saline water from the sea and receiving fresh water from rivers, land run-off or seepage” (Davidson et al. 1991). They are complex systems, subject to a usually twice daily tidal rise and fall, they may have sand dunes or gravel structures enclosing sheltered shallow mud and sand shoals and salt marshes. They are particularly extensive in lowland areas with abundant sediment and a macro-meso-tidal range. Particularly large sites occur in the southern north sea, (in and around the Thames Basin, the delta region of Holland and in the Wadden Sea).

Estuarine fauna. A key component in the development of the ecological value of coastal wetlands, especially tidal estuaries, is their high productivity. This is derived from in situ

primary production of salt marshes and in estuarine waters, as well as inputs from the land and the sea. This abundant source of food can result in very large numbers of a few dominant organisms. Typical densities on muddy shores of the mud snail *Hydrobia ulvae* can be up to 120,000 individuals present per square meter. The burrowing amphipod *Corophium volutator* is also numerous with up to 60,000 individuals per square meter. The segmented worms *Nereis diversicolor* (a ragworm) and on more sandy shores *Arenicola marina* (lugworm), are also often abundant and of particular importance as prey for wintering wading birds. In this context, estuaries in north west Europe are especially valuable and frequently support nationally and internationally important numbers of water birds (wildfowl and waders). Some indication of the significance of these estuaries can be gleaned from the location of the main wintering populations of the knot *Canutus canutus islandica* (Fig. 6).

While these wintering bird populations are often the most obvious visible manifestation of the productivity of a wetland system a range of other species occur. These include sea fish using the shelter of the estuary to spawn, or as nursery areas. Diadromous fish are specialists of the estuarine environment. Catadromous species such as *Anguilla anguilla* (the common eel) move from freshwater to the sea where they spawn, passing on the way the salinity gradients in the estuaries and deltas.

Europe, Coastal Ecology,

Fig. 6 Distribution of the main wintering sites of the knot *Canutus canutus islandica*. (Adapted from Doody 2001b)

other figures (Smit and Piersma 1989)

In contrast an anadromous species such as *Salmo salar* (salmon) develops from eggs shed upstream in rivers. A major part of its life is spent outside the home rivers at sea. Important feeding areas are in the Atlantic along the west coast of Greenland, above the Faroe Islands, in the Norwegian Sea, and possibly in the Barents Sea. In the Baltic, the Curonian Lagoon has 46 freshwater, migratory, and marine fish including the Baltic salmon, reflecting its importance for these species.

Deltas and Lagoons

Coastal deltas and lagoons are most characteristic of micro-tidal regions (with a tidal range < 2 m), and hence in Europe are particularly abundant around the shores of the Baltic, Mediterranean, and Black Seas. Deltas are sedimentary coastal plains built up from material brought down by rivers to cover shallow offshore areas creating sedimentary features which protrude beyond the normal limit of the coastal margin. They are best developed in micro-meso-tidal areas

where wave action is the dominant force in building the sand dunes, barrier islands bars, and salt marshes. Lagoons are shallow, virtually tideless, pond-or lake-like bodies of coastal salt or brackish water that are partially isolated from the adjacent sea by a sedimentary barrier, but which nevertheless receive an influx of salt water from that sea (Barnes 1980; Guélorget and Perthuisot 1992). Although they are mostly found in micro-tidal seas, they are also present on some macro-tidal coasts – such as the northern North Atlantic – where offshore deposits of gravel are to be found. Gravel then replaces the sand of micro-tidal seas as the barrier material. Europe possesses the smallest proportion of lagoonal coastline of any continent, with only 5% of its coast in this category (Cromwell 1971). Several deltas, for example that of the Danube (and Nile), have developed within – and have now largely or completely obliterated – former lagoons enclosed by barrier-island chains. The limans of the Black Sea coast receive their salt input via seepage.

Fauna. Deltas and lagoons are also important for a variety of water birds. They support waders, wildfowl, grebes, and similar marshland birds many wintering or on passage, as well as a considerable number of nesting species. Among these black-winged stilt *Himantopus himantopus*, avocet *Recurvirostra avosetta* and herons, including purple heron *Ardea purpurea* and large populations of a few species of breeding duck are significant. However, it is the spectacular flamingo *Phoenicopterus ruber roseus*, which is most readily appreciated by anyone visiting the Camargue or the Ebro Deltas in the western Mediterranean. Numbered in thousands in the Camargue it is a species dependent on wetlands which periodically dry out and become hypersaline. These conditions naturally occur in North Africa and the Mediterranean but it is the juxtaposition of “natural” lagoons with “artificial” salinas which provide especially suitable nesting conditions (Sadoul et al. 1998).

The lagoons also support invertebrate and fish faunas. These may include essentially freshwater or marine/estuarine species capable of withstanding a degree of brackishness as well as specialist lagoon species. Among the marine fishes are sea bass *Dicentrarchus labrax* and sole *Solea vulgaris* while carp *Cyprinus carpio* and pike *Esox lucius* live in freshwater. Eel *A. anguilla* and mullets (Mugillidae) bridge the salinity gap.

Salt Marshes

Salt marshes include all halophytic plant communities and their associated animals, which are influenced by sea water. Typically they are regularly inundated by the tide, have sometimes rapid accumulations of fine sediment and in the absence of enclosure, include transitions to nontidal vegetation. They are at their most extensive on flat tidal plains in sheltered locations where abundant sediment is deposited and wave action restricted (estuarine marshes). These conditions are most favorable to the establishment of the pioneer salt marsh plants such as *Salicornia* spp., *Suaeda* spp. and *Spartina* spp. which are among the most frequent colonists in northern latitudes. Lagoonal marshes occur in association with lagoons and are most extensive in the micro-tidal areas. Salt marshes also occur on beach plains behind exposed or partially protected beaches and in the lee of barrier islands. In some areas where sediment is restricted or (as is the case on some rocky shores and cliff tops) absent, inundation is intermittent and dependent on storms or extreme high water levels. In these situations, “perched” salt marshes on exposed cliffs and narrow saltings of rocky shores “beach head” and “loch head” salt marshes have vegetation similar to the typical salt marsh but without their rapid sedimentation (Doody 2001a).

Distribution in Europe. Salt marshes occur throughout Europe and are particularly associated with the major macro-tidal estuaries of the southern North Sea and south and west England (Dijkema 1984). Elsewhere in the northwest they occur as scattered small sites associated with rocky coasts. In the Baltic, they are more restricted, partly because

of the very low salinity within this sea (Dijkema 1990). In the Mediterranean, all the major deltas have extensive salt marsh communities. Elsewhere they again occur as scattered sites, though here less frequent than in the north. Their distribution is closely related to that of the coastal wetlands.

Vegetation succession. A key element in the development of salt marshes in sediment rich areas is the process of succession. A sequence of communities tolerant of different degrees of tidal submergence may develop, together with transitions to other, terrestrial vegetation. Transitions may be to reed swamp sand dune, gravel, freshwater, or woodland. This natural transition may be truncated by the construction of sea walls or other coastal defenses, with the loss of these upper salt marsh transitions and their associated wildlife. In some areas where a saline influence continues landwards of sea walls on enclosed unimproved salt marshes, coastal grazing marshes with brackish ditches may develop.

The early stages of colonization are represented by two main community types (European Commission 1999), namely: ***Salicornia* and other annuals colonizing mud and sand** and ***Spartina* swards (*Spartinion maritimae*)**. These are typically referred to as pioneer marsh colonizing the lower levels of the tidal flats, most frequently inundated by the sea. Under these conditions, areas of mud, exposed for several days, are required for the early colonizers to become established. The communities which develop are composed of a few, mostly annual species occurring in mono specific stands, or in simple combinations. These typically include *Spartina* communities, most frequently *Spartina anglica* stands of *Salicornia* spp., *Suaeda maritima* and *Aster tripolium* with *Puccinellia maritima* dominant. They are most frequently found in the macro-meso-tidal areas of the northwest.

The next stage in the successional process is typically referred to as mid-marsh. The distinction between low and mid-marsh is blurred but as the tidal height of the marsh increases additional species occur. These are dominated by the shrub *A. portulacoides* in the absence of grazing with increasingly *Festuca rubra* on grazed marshes. There is a wide variation in the composition of these communities and *Juncus gerardii* is another characteristic species. The presence of abundant *Armeria maritima* gives many marshes in the northwest a visually distinct appearance with a close-cropped, pink sward in summer.

The development of upper-marsh in the absence of enclosure provides some of the richest plant communities. Mid-upper marshes in the northwest are collectively classified within community type. **Atlantic saltmeadows (*Glaucopuccinellietalia maritimae*)**. The presence of a number of species such as *Suaeda vera*, and *Frankenia laevis* in southeast England, more frequently found in Mediterranean regions suggest an overlap in distribution with. **Mediterranean salt meadows (*Juncetalia maritimi*)** and

Mediterranean and thermo-Atlantic halophilous scrubs (*Sarcocornetea fruticosi*). Transitions to swamp also occur in the absence of enclosure and are usually dominated by *Scirpus maritima* and *Phragmites australis*, which can be extensive in the upper reaches of estuaries. These communities form important transitions and may be particularly rich, especially where freshwater seepages or transitions to other habitats such as sand dunes occur. In the Baltic, the low salinity and micro-tidal range of the sea restricts the presence of the pioneer communities and extensive swamps dominated by *Phragmites* are more prevalent (Dijkema 1990). Similarly in the Mediterranean the extent to which a true succession develops is restricted and narrow zones of a few mid-marsh species quickly merge into more extensive swamp. Some of the best examples of these occur in the still relatively undeveloped coastal deltas of northern Albania.

Fauna. Salt marshes present difficult environments for colonization by invertebrates due to changes in salinity and humidity caused by periodic tidal immersion. The fauna is a mixture of marine, freshwater and terrestrial species, which are adapted in various ways to the stressful environment. Marine species tend to occur lower down the marsh and often burrow to avoid desiccation. Terrestrial and freshwater species occur mostly in the upper marsh and transition zones, and have adapted to, or avoid immersion in saline water. The presence of individual invertebrate species is often closely associated with the type of vegetation which occurs.

Successful breeding by a variety of birds occurs on the upper levels of unenclosed salt marshes following the high spring tides in April and May. Although early nests may be destroyed by high tides, at least one brood is usually possible. The structural diversity of the marsh is also of crucial importance to some species such as redshank *Tringa totanus* and particularly high populations may be present in the best habitats. In winter, many of the most numerous species of wader feed almost exclusively on the invertebrates in the mud flats at low tide and are not dependent on the salt marshes as their main food supply. However, some also use the salt marsh for roosting at high tide, or as supplementary feeding around the pans and bare areas on the marsh (e.g., dunlin *Calidris alpina* and knot). Only the redshank and snipe, of the wading birds, use salt marsh in preference to the exposed tidal flat, probably because they like to be sheltered from view by the cover of vegetation. For these species the salt marsh represents the primary feeding location throughout most of the tidal cycle.

Other species, mainly grazing ducks and geese use the salt marsh as a source of food. The geese seek out open areas with close-cropped or low vegetation. Even here there are distinct preferences, and while the brent goose feeds on Eel-grass (*Zostera* spp.) in the low marsh, the stronger grey-lag goose feeds on the tougher grasses of the marsh itself. Of the ducks the wigeon feeds on both low and high marsh, normally at the

waters edge. For most of these species the more palatable grasses favored under high stocking densities of cattle and sheep, are important to the continued use of the salt marsh by the grazing ducks and geese.

Sand Dunes

Sand dunes develop wherever there is a suitable supply of sediment (within the size range 0.2–2.0 mm) which is moved onshore by the tide and then blown inland to form accumulations varying from a few centimeters to 40 m or more thick. The type of sand dune which develops depends on the underlying topography and climate. In most locations in the temperate regions of the world, vegetation plays an important role in the growth of the typical dune landscape, facilitating the accumulation of sediment (Ranwell and Boar 1986). Bay dunes are the most common form and are associated with indented coastlines, often between headlands. Backshore dunes can be large and occur when both dominant and prevailing winds blow sand inland. On especially exposed sites, coastal cliffs may be covered with a veneer of sand blown up over the cliff to create “climbing dunes.” Barrier islands tend to occur in exposed locations and may be built on gravel bars. Ness dunes, including cusped forelands, occur where prevailing and dominant winds are in opposition. Sometimes progradation may be quite rapid and a series of low dune ridges form, interspersed with wet hollows. These are also found in areas where sea level is rising relative to the land as in southeast Norway, northeast Scotland, and Northern Ireland. Spit dunes occur when sediment is deposited at the mouth of an estuary. They take a variety of complex forms depending on the action of waves (longshore drift) and the force of the river flows to the sea. These also include the dune forms associated with deltas in micro-tidal seas.

Distribution in Europe. Sand dunes are distributed throughout Europe (Fig. 7). In the areas where sediments are restricted there are a relatively large number of small sites, as in northern Norway and on the rocky, cliffed coasts of the exposed shores of the Atlantic from western Ireland to Spain, the karst coasts of the Mediterranean, and in the Black Sea. In the west where there are abundant coastal sand deposits, prevailing westerly winds blow the sand grains onshore to create large backshore systems such as those of the Outer Hebrides in Scotland. These include some of the best and largest examples of the extensive cultivated sandy plain or machair, also present in the west of Ireland. In northern Denmark massive accumulations of sand are forced onshore under the action of the prevailing winds from the North Sea. In France on similarly exposed coasts the dunes stretch many kilometers inland. Here, the area known as “Les Landes” has a special significance, and is one of the most extensive dunes in Europe.

On the North Sea coast and in the northern Baltic, dunes develop on a coastline, which is rising relative to sea level.

Europe, Coastal Ecology,**Fig. 7** Distribution of sand dunes in Europe. (Adapted from Doody 2001b)

Here, they are generally prograding with ridges becoming established as a sequence lying “parallel” to the coast. They are sometimes interspersed with damp hollows in which dune slack vegetation develops. In eastern Scotland some large examples occur, as at Culbin Sands a system with in excess of 4000 ha, one of the largest areas of blown sand in Great Britain.

In the southern Baltic and southern North Sea where glacial sediments are particularly abundant, sand dunes are also extensive, for example, they make up 80% of the coastline of Poland. The predominant dune type is represented by sand bars and spits, which lie parallel to the coast (Poland and Wadden Sea). In southern Portugal and Spain, the dune systems also include barrier islands and spits. Rivers bring the sediment to the sea, which is then reworked by wave and tidal action and blown onshore. One of the most important dune systems in Europe, lies within the Doñana National Park in Southern Spain. The park consists of beaches, foredunes, high mobile dunes (up to 30 m), and stabilized dunes which enclose a major wetland.

On the Mediterranean and Black Sea coasts dunes are often found in association with deltas. In Italy, dunes probably originated during the thermal optimum after the last glaciation (5000 years ago). They have since been broken by rivers and their subsequent development has been a product of natural

erosive forces and human activity. Today dunes are present around the whole coastline but only in a few protected areas, like the National Park of Circeo, can natural development be seen. Along the Greek coast there are many places where sand dunes cannot develop because the hills or mountains outcrop as rocky coastlines near to the sea. Sand dunes tend either to occupy a narrow fringe bordering flat areas of land or exceptionally form extensive dunes up to 10 m height, as in Western Peloponnesus.

Vegetation succession. The vegetation of sand dunes in temperate regions such as Europe can be grouped according to the successional sequence from the beach inland. These have been defined for the north west coastal areas as follows:

Strandline: This includes vegetation along the high tide line.

It is usually ephemeral, salt tolerant and composed of a limited number of species;

Foredune: The first stage in sand deposition occurs here. The vegetation is limited in species diversity, dependent on its ability to withstand the influence of salt spray and trap moving sand;

Yellow dune: This represents the main and usually most rapid phase of dune growth. *Ammophila arenaria*, the main dune forming species, is able to withstand rapid burial by sand;

Dune grassland: Stabilized dune vegetation dominated by species of grass and herbs develops under the influence of grazing and in a moist climate. It is mostly found in northwest Europe;

Dune heath: Occurs on sand dunes where the calcium carbonate content of the soils is low, either because the original sand has a high proportion of silica or where leaching has taken place;

Scrub: Areas with low shrubs. These include woodland understorey species in the northwest and the “maquis” and other similar vegetation in the Mediterranean;

Dune slacks: Vegetation which develops under the influence of high water table and is often completely flooded in winter;

Woodland: Natural forest with various pine species or deciduous trees such as oaks. In most areas natural woodland is scarce.

The European Habitats Directive recognizes three major types of vegetation (European Commission 1999). Of these the dunes of the “Atlantic, North Sea and Baltic” include at least 11 distinct types and those of the Mediterranean coast, 7. Most of the sand dunes described for northwest Europe appear to have a sequence of vegetation types which potentially includes all the more important successional communities from strandline (driftwalls) to yellow and grey dune, dune pasture and scrub, described above. (In areas where beach erosion is occurring some of the early stages of succession may be absent.)

The sequence of vegetation on the mid-Atlantic coast is similar to that occurring in the northwest. In the north of France, some of the botanically richer areas occur where dunes are composed of calcareous sand and lie against to chalk cliffs. The further south the dunes are formed, the more the southern elements of the flora appear.

On the Mediterranean coast the zonation described above is much less obvious. While *A. arenaria* still plays an important part in dune establishment, communities with dry grasslands and scrub are more prevalent. The following are recognized from the Manual of European Union Habitats (European Commission 1999).

Crucianellion maritimae fixed beach dunes
Dunes with *Euphorbia terracina*
Malcolmietalia dune grasslands
Brachypodietalia dune grasslands with
annuals
Coastal dunes with *Juniperus* spp.
Cisto-Lavanduletalia dune sclerophyllous scrubs
Wooded dunes with *Pinus pinea* and/or
Pinus pinaster

Fauna The dune fauna is not especially rich or abundant though the variety of slope, aspect and vegetation structure, coupled with the dynamic nature of many systems, make dunes one of the most suitable habitats for a range of

invertebrates requiring open conditions. They are also frequented by warmth-loving species, which bask on the dry warm slopes even in the more northern latitudes. Hymenoptera (especially wild bees, digger wasps, spider wasps, and other solitary wasps) are able to build nests easily in the soft sand and are often found dwelling in sand dunes (Haeseler 1989, 1992).

The dune avifauna includes breeding colonies of terns such as the sandwich tern *Sterna sandvicensis* and the little tern *Sterna albifrons* which nest on open sand. Other species such as the eider duck *Somateria mollissima* and the shelduck *Tadorna tadorna* nest in the ground vegetation in the north. Further south (including eastern Spain) tree nesting species of heron, such as the squacco heron *Ardeola ralloides* and the purple heron *Ardea purpurea* can be found.

Rabbits *Oryctolagus cuniculus* occur in abundance in all areas and are stock food for fox *Vulpes vulpes* populations of which inhabit mainland dunes. Polecat *Mustela putorius*, weasel *Mustela nivalis*, several species of bats, voles, mice, and shrews also occur in most of the areas, while the roe deer *Capreolus capreolus* and red squirrel *Sciurus vulgaris* are less frequent. Among reptiles and amphibians are sand lizard *Lacerta agilis* natterjack toad *Bufo calamita* and the edible frog *Rana esculenta*.

Gravel

Gravel is the term applied to sediments larger in diameter than sand but smaller than boulders. A predominant particle size of over 2 mm separates gravel from sand (King 1972) whereas at much over 200 mm diameter, boulders approximate to cliff habitat. Four environmental factors are responsible for the growth of a gravel beach. There must be an available supply of sediment in the size range mentioned above. At the same time waves, wind, and tidal currents should be favorable for its movement. Since this coincidence is unpredictable, considerable periods of time may exist when no movement takes place, these are interspersed by times of marked activity resulting in stable and mobile gravel habitats varying both in time and space.

Geomorphologists and ecologists have recognized five categories of gravel structures which vary in their oceanicity and therefore in their ecology. The simplest and commonest type is the fringing beach forming a strip in contact with the land along the top of the beach. Gravel spits form where there is an abrupt change in the direction of the coast. They often contain recurved hooks and a recurved distal end, a result of deflection of waves by refraction. Bars or barriers are effectively spits which have formed across estuary mouths or indentations in the coast. These three structures are basically foreshores, regularly washed by spray and storm waves and therefore possessing only limited or ephemeral vegetation over much of their area. Cuspate forelands and offshore barrier islands, on the other hand, are larger structures

Europe, Coastal Ecology,
Fig. 8 Dungeness southeast
 England – a cusped foreland

and are more terrestrial in nature. The former develop when gravel is available in large quantities and piles up in front of fringing beaches or spits and is then driven landwards by storm waves to form a series of roughly parallel ridges. Where wave approach can from two directions only, such apposition beaches will form into cusped forelands (Fig. 8). Large masses of gravel may also form offshore barrier islands under conditions of shallow water and low-energy environments such as in the North Sea and the Baltic.

Distribution. Gravel deposits occur throughout Europe, especially in the north and west. Fringing beaches are widely distributed, though often small and narrow. Larger gravel structures occur as isolated and discrete entities. (Doody 2001b). In the north, the fjords and sea lochs in both the meso-tidal and micro-tidal areas of the Atlantic, North Sea, and Baltic Sea support long stretches of gravel foreshores. Individual, more substantial structures are scattered throughout the area. The situation in the United Kingdom illustrates the nature of this occurrence (Fig. 9). This is derived from extensive surveys undertaken in the 1990s and organized by the statutory conservation body, the Nature Conservancy Council.

Vegetation. Two plant communities identified in the European Union Habitats Directive (European Commission 1999) help to define these formations: **Annual vegetation of drift lines** and **Perennial vegetation of stony banks**. Gravel shore vegetation includes *Mertensia maritima* prevalent in the north and *Glaucium flavum* and *Matthiola sinuata* in the south. Mobility is an over-riding consideration and the species which colonize are able to withstand periodic disturbance. These include *Lathyrus japonicus* and *Crambe maritima* colonizing the gravel just above the high water mark where the shore may remain stable for periods of 3–4 years. *Crambe maritima* is constant in the three sub-types of **Perennial**

Europe, Coastal Ecology, Fig. 9 Distribution of gravel shores in the United Kingdom, some key sites are named

vegetation of stony banks, for the Baltic, Channel coast, and the Atlantic, respectively. Besides stability (or its converse mobility) beach composition and especially the amount of fine material present in the gravel matrix is another principal factor influencing the type of vegetation namely:

1. Gravel without matrix (relatively uncommon) – Vegetation is limited to encrusting lichens and the most tolerant angiosperms such as *L. japonicas*;

2. Gravel with a sand matrix – Dry yet stable conditions, contains species such as *Lotus corniculatus* and *Honckenya peploides*;
3. Gravel with a silt–clay matrix – Ecologically related to salt-marshes but with freer drainage. The vegetation is similar to that of saltmarsh levées with *A. portulacoides* or *Glaux maritime*;
4. Gravel with an organic matrix – Rotting seaweed is nutrient rich and supports populations of species that arrive as seed within tidal debris. Species include *Beta maritima* or *Atriplex* spp. where there is little drainage from the land, or with more humic soils reed *Phragmites communis* or *Iris pseudacorus* swamp may be present.

Fauna. The fauna associated with gravel structures largely consists of invertebrates (Shardlow 2001) and avifauna. In the case of the former large numbers of species, such as bumble bees are found. Gravel beaches and structures provide suitable habitat for a small number of other species. These are generally ground nesting birds (Cadbury and Ausden 2001) which make a simple scrape where they lay their camouflaged eggs. The importance of gravel as a habitat for breeding terns has led to the conservation of several sites and the need to create areas protected from human trampling affects. Few vertebrates other than domestic herbivores are found on gravel sites except hares and rabbits, though in some places foxes are important predators of ground nesting birds.

Human Influences

This entry along with many text books describe coastal habitats in terms of their ecological or geomorphological development. Salt marshes and sand dunes, in particular are described as exhibiting primary succession. Classic studies in Great Britain covered salt marshes and sand dunes on the North Norfolk coast. All emphasized the natural status of the vegetation in areas where ecological processes appear to have been relatively free from human influence. The vegetation was thus described as a series of community types progressing from the early pioneer stages to more complex forms related to the physical factors influencing their development. While this is in part true, it is also the case that much of Europe's coastline has been influenced in one way or another by human activity. A few examples are discussed below.

Sea Cliffs and Slopes

Apparently inaccessible steep-sided sea cliffs and slopes are often seen as virtually unaffected by human activity. Certainly difficulties of access, low productivity, associated with a harsher climate mean that the harder rock of the north are less built on than their counterparts in some parts of the

Mediterranean. However, grazing is and has been a traditional activity and even cliffs on more inaccessible islands have been and in a few cases continue to be plundered for sea birds and their eggs.

Sand Dunes

Major tourist development, especially along the Mediterranean coast, has destroyed many sand dunes. Building directly onto the beach in some cases has completely obliterated some areas while sand extraction for use nearby has also taken its toll. Another activity is planting with non-native trees, especially conifers, to stabilize them. This has affected many systems throughout Europe and while the dune form is retained most of the dune plant and animal species are lost. One exception to this general picture is the large dune systems which have developed in association with major deltas on the coastline of Albania and in some parts of south east Turkey. Here, many different dune forms are present with a maximum height of about 50 m and width of up to 4.3 km, including huge beach plains with embryo dunes, parabolic dunes, blowouts, dune slacks, lakes, secondary barchans, and dune fields. They also include complete transitions to pine woodland with native *P. pinea* and *Pinus halipensis* as the forest tree. They are among the most important dune areas in Europe.

Secondary Habitats Coastal Grazing Marsh and Salinas

The partial enclosure of salt marsh by the erection of a small earthen bank was probably one of the first human activities directly affecting coastal habitats. The aim was to extend the period of summer grazing by livestock (cattle and sheep), by preventing over-topping on spring tides. As the early techniques of enclosure improved, larger clay or earth banks were constructed enclosing consolidated salt marsh excluding the tide from larger areas. Historically the land was subsequently used as pasture, with little or no further "improvement". These areas of coastal grazing marsh are defined by the presence of permanent and semi-permanent grassland, drainage ditches, and enclosing earth dikes. The wildlife interest has developed alongside the traditional use of the area for agricultural.

The production of salt is one of the oldest industries known to man. Industrial salinas are large, artificial, and complex lagoon systems and a major source of salt produced today. The principal aim of any salt company is to produce a maximum tonnage of salt per annum to meet the demands of commerce and industry. However, these artificial ecosystems are in fact, wetlands of international importance and areas with a rich and diverse flora and fauna, vertebrate and invertebrate communities. They host important breeding populations of aquatic birds, besides rare and endangered species. The special nature of Mediterranean salinas make them vitally important resting and refuelling sites for many

thousands of shorebirds migrating between the Palearctic breeding grounds and their winter quarters in Africa (Sadoul et al. 1998).

Grazing and Other Management

A key feature of many habitats throughout Europe is the long history of exploitation by human kind, including grazing by domesticated stock. This has had a profound influence on the type of vegetation which has developed. In the northwest grazing (by rabbits cultivated in warrens) helped to create species rich calcareous dune grassland and heathland, preventing the natural progression to scrub and woodland. In areas formerly used for grazing by domestic stock a reversion is taking place to secondary mixed scrub, broad-leaved woodland and pine forest. This is particularly prevalent in Finland today where invasion of open land by pine forest with *Pinus sylvestris* is common. Prior to this, open vegetation was maintained by the grazing of domestic animals.

Grazing and burning are intimately bound up with the development of the low, thorny scrub vegetation which predominates in the Mediterranean. It is also clear that many of the major deltas would not be as extensive without the influence of deforestation in the hinterland. Thus it can be seen that the rich diversity of habitats and associated species, which exist along the coastline of Europe are influenced to a greater or lesser extent by human activities. At the other extreme major developments including tourist growth in the Mediterranean has greatly reduced the ecological and landscape diversity of many areas to the detriment of wildlife and cultural heritage. The way in which this has altered the coastline of Europe and the approaches being adopted to monitoring the impact of development and policy initiatives designed to protect it is the subject of the entry on Monitoring, Coastal Ecology.

well as coastal cementation like eolianites and beachrocks. Because of the rather long and complicated geologic and tectonic history of the European continent, the coastlines are greatly differentiated. Their total length in natural scales is several 100,000 km. Many of the scientific terms in coastal sciences derive from European examples, like ria, fjord, canale, tombolo, or Thyrrenian, Sicilian, and Calabrien for Pleistocene sea-level highstands.

Definition

The coastlines of Europe cover a latitudinal range of 45° reaching from 80°N in Spitsbergen to 35°N in southern Crete, Greece. Thus, nearly all coastal types except for mangroves and coral reefs are present in Europe, including arctic ice coasts with calving glaciers, drifting sea ice contact and permafrost decay along cliffs on Spitsbergen, or young volcanic coastlines on the Aeolian Islands of Italy or Santorini/Greece. Processes of salt weathering associated with tafoni are present at the Costa Brava in Spain and the islands of Corsica and Sardinia or SW Turkey, and biogeneously formed coastal forms (Kelletat 1997) including vermetid boiler reefs and microatolls are characteristic on Crete islands (Greece) as

The Framework of Coastal Forming in Europe

The geology of Europe varies from very old structures, the Proterozoic shields of granite and gneiss in Scandinavia, to rather young like the vivid neotectonic areas in the eastern Mediterranean (Pirazzoli et al. 1996). The orogenic belts of the Caledonides are still visible in the coastal configuration of Scotland (Fig. 1), the Variscids in southern England, and the imprints of the alpidic orogenesis, can be observed along nearly all coastlines of the Mediterranean (Figs. 2 and 3). Areas of longer subsidence are marked by large embayments like the North Sea basin, the Bay of Biscaya, or the intracontinental sea of the Baltic and the intercontinental sea of the Mediterranean. Extremely resistant silicate rocks

Europe, Coastal Geomorphology, Fig. 2 Horst and graben structures dominate the coastal configuration along the southern part of the Peloponnese/Greece (Credit: Google Earth)

survived thousands of years of wave attack, whereas Pleistocene moraines or Holocene dunes suffer from strong erosion and abrasion. Vertical movements influence coastal development in many regions, but by different causes. Among them are long-lasting and ongoing glacio-isostatic uplift in Scandinavia (nearly 300 m, with a modern maximum of 9 mm/year, and Fig. 4), Iceland and Scotland (both with more than 120 m), salt intrusion in small places of the North Sea basin (e.g., Heligoland), active horst and graben structures in the eastern Mediterranean (Fig. 5), sediment load in large deltas, or local subsidence by gas and water drilling in the Venice area. All processes cause their respective characteristic coastal shape.

Furthermore, exogenic factors of coastal forming are manifold and here in particular climate and its influence on the ocean. The spectrum ranges from frost climates of average annual temperature below -2°C and sea ice cover of 9 months to nearly 30°C of surface water temperature in summer. Extreme humid conditions with over 2,000 mm of precipitation are typical for NW Europe, but less than 200 mm/year of precipitation is measured in eastern Crete (Greece), where evaporation exceeds precipitation by a factor of 10. The salt content of seawater ranges from nearly 0% in the inner Baltic Sea to at least 3.9% in the eastern

Mediterranean. Moreover, wind and wave spectra are very different: in the west, strong winter storms may cause severe destruction and flooding (Clarke and Rendell 2009; Weisse et al. 2014; Masselink et al. 2016), while in small bays of the Baltic or the Mediterranean wave action is insignificant. Tidal range and the strength of tidal currents differ along a west-east gradient: spring tide range is highest around southwestern England and the Brittany coast of western France (Fig. 6), reaching more than 10 m, but in the Baltic and the Mediterranean it usually is less than 0.5 m to zero. Nevertheless, low air pressure and extreme winds may cause storm surges up to 3 m above datum in these enclosed basins. Even tsunami impacts can be detected such as along the Algarve coast of southern Portugal, southern Atlantic Spain, Mallorca Island, Apulia, Greece, Cyprus (Kelletat and Schellmann 2002), or in marshes in Scotland and in coastal lakes of western Norway by the Storegga event about 8,100 BP (Bondevik et al. 1997).

Specific Coastal Regions

European coastal regions with a specific environmental or geomorphic factor are illustrated in Fig. 6: northern Europe

Europe, Coastal Geomorphology, Fig. 3 The Adriatic coast along Croatia is a typical area of parallel anticlines from Mesozoic folding, drowned by subsidence and postglacial sea-level rise to form canale and vallone coastlines (Credit: Google Earth)

including Scotland and Iceland present coastlines of emergence by glacio-isostatic uplift between near 0 and 285 m. Nevertheless, those coastal forms are predominantly marked by ingression, so that fjords (Fig. 7), fjärds, bodden, förden (Fig. 8), or partly submerged roches moutonnées as skerries, as well as partly drowned eskers, end moraines, or drumlins (Fig. 9), are characteristic (Duphorn et al. 2011). Glacial erosion has carved bedrock far below sea level, and therefore the late- and postglacial transgression is not compensated by late- and postglacial uplift. The area of glacio-isostatic uplift mostly corresponds with glacially sculptured coastal landscapes, in which the forms from the last glaciation are much clearer than those from the penultimate glaciation, which are smoothed by periglacial processes during the Weichselian. Another *specificum* of the northern sections in Europe is frost action along the coast including drifting sea ice contact, in particular, in the inner and eastern Baltic as well as in the Barents Sea and in some inner parts of northern Norwegian fjords, where Gulf Stream influence is minimal and freshwater input is important.

Pleistocene glaciations have left behind specific materials along the coasts: moraines are washed out and show boulder beaches as in the Åland archipelago between Sweden and

Finland or along the southern Baltic coastline, partly pushed into ridges by drifting sea ice. These boulders are an important natural protection against surf beat and erosion. Glacial outwash and fluvioglacial deposits are characterized by gravel and sand, which dominates the southern coasts of Iceland as well as the west coast of Denmark or the northwestern coast of Germany and the Netherlands. If sand supply from the ice ages is abundant, barrier islands with extended beaches are developed, accompanied by coastal dunes. Similar conditions are also found along the southern Baltic coastlines (Baker et al. 1990).

In contrast to formerly glaciated landscapes, fluvial-formed landscapes are dominant in the south of Europe, where rivers have carved into older bedrock during low sea levels. Postglacial transgression has transformed these valley mouths into rias as in southern Ireland, England, Brittany in France, and in NW Spain, some of them widened by tides and waves into estuaries as in the mouth of the rivers Elbe (Germany), Thames (England), or Seine (France).

A third representative coastal area in Europe is formed due to faulting processes associated with horst and graben structures such as southern Greece including the Aegean Sea (Fig. 5). A vivid neotectonic is still dislocating coastal

Europe, Coastal Geomorphology, Fig. 4 Glacio-isostatic uplifted beach ridge systems (back into late-glacial times), Varanger Peninsula, NE Norway (Credit: Google Earth)

sections vertically (Pirazzoli et al. 1996, see also Fig. 10). In more downward-moved parts, coastlines of ingress with drowned medium-to-steep slopes are common (Fig. 11). Here, canals (Fig. 3) and short rias, transformed by karst and marine erosion into calas of different shapes, are developed, and as well drowned karst features like dolines or poljes dominate (Fig. 12). In contrast, cliffs and shore platforms (Figs. 13 and 14; Erdmann et al. 2015; Gomez-Pujol et al. 2014; Robinson and Lageat 2006) and coastal terraces are typical for the uplifted parts of the landscape. The areas of (Pleistocene) uplift in southern Europe often correspond with young orogenic structures, representing excellent examples of Pleistocene marine terraces up to several 100 m above sea level today.

As limestone is the predominant rock type in the Mediterranean area, coastal bioerosion with notches (mostly by grazing *Patella*, Fig. 9) and rock pools (by grazing *Littorina neritoides*) and bioconstruction by calcareous algae (e.g., *Neogoniolithon notarisii*) and vermetids (e.g., *Dendropoma petraeum*, Fig. 15) are widely common in this part of the European coast. Another specification is the extended distribution of younger Pleistocene eolianites along the Mediterranean coasts, whereas Holocene beachrocks are mostly restricted to the hot and dry sections of the eastern Mediterranean (Briand and Maldonado 1997).

There is only one area of high tides in Europe, located between southern England and the Brittany coast of France where the spring tide range reaches around 10 m, diminishing to the inner German Bight and Scotland to medium values of 2–4 m. These areas may show extended tidal flats, with a sandy matrix where wave action and tidal currents are strong and muddy in regions of weaker water movements (Fig. 16; Ehlers 1988; Hillen and Verhagen 1993). The growth of green and brown macro-algae (*Fucus* sp., *Laminaria* sp., and others) along the rocky shores is characteristic for the cooler European coastlines from northern France including the British Isles and Iceland to northernmost Norway (but excluding the Baltic). They partly give protection against strong surf beat, whereas in the Mediterranean, sea grass may form a thick carpet on beaches after winter storms. Along parts of the Swedish, Finnish, Polish, or German coastline with a low salt content of seawater, coastal freshwater swamps with *Phragmites* sp. occur.

Coastal Forms and Sediments

The differentiation of coastal forms along the European coastlines is visualized in Fig. 17 giving an impression of

Europe, Coastal Geomorphology, Fig. 5 Stepwise uplifted Gramvousa peninsula as a horst structure in NW Crete (Greece), looking to the south. Main fault line to the west (right), with Balos lagoon area,

the general form of bays: rias and estuaries by fluvial action as in Fig. 18; fjords, fjärds, förden, and bodden by glacial sculpturing; canale by folding and faulting control; cala by karst and abrasion; or lagoons with barriers and spits up to 90 km in the eastern Baltic by longshore drift). The map also represents the different coastline types: rocky coastlines with cliffs (and intertidal platforms), sandy shores with beaches (including areas with beachrocks), muddy ones in tidal flats, deltaic by fluvial progradation (as in the areas of low tides and surf of the Mediterranean), or biogenic structures along limestone coasts with poor sediment supply.

Deeply incised fjords are the main coastal features of northern Iceland, northwestern Scotland, and nearly all of Norway except of the easternmost parts where cliff sections around the North Cape and the Barents peninsula occur. In Scotland and the central north coast of Iceland, wider rocky embayments in a low and hilly landscape smoothed by Pleistocene glaciation reveal more aspects of fjärds, which are typical for the Swedish coastline along the Baltic and some parts of Finland. Here, an old peneplain is slowly dipping seaward. Numerous skerries decorate all rocky Scandinavian coastlines, whereas to the periphery of former

glaciation, morainic sediments and fluvioglacial deposits dominate. Thus, the landscape is either characterized by partly drowned eskers, drumlins, and end moraines, which are mostly well preserved in areas with low surf energy conditions, such as in the island archipelago of southeastern Denmark, or fast receding cliffs may have been developed like along the southern shores of the Baltic. As a rather unusual feature in the Scandinavian coastal landscape the so-called strandflat exists as an undulating rocky plain surrounding most of the coasts of Norway but occurring likewise in northwestern Iceland. The form originates from a glacially smoothed old peneplain now situated around sea level with a medium width of 16 km and a maximum one of 40 km. Roches moutonnées are the dominant features, and old inselbergs may rise from the peneplain to several 100 m of relative height. Outwash plains (sander), fed by meltwater and glacial-burst floods, are typical for the southern part of Iceland. Therefore, the coasts show beaches and even barriers and lagoons. Along the southern shores of the Baltic spits fed by longshore drift from the west (Fig. 19), lagoons and intercalated cliffy sections occur. Along the Polish coast 52% are sandy beaches, 28% are freshwater swamps, and only 20% show cliffs. At the German Baltic

Europe, Coastal Geomorphology, Fig. 6 Map of the European coastlines showing special environmental parameters

coastline, this type gradually changes to ingressive forms from glacial and fluvio-glacial origin like bodden and förden (Fig. 8).

The longest section of muddy and sandy tidal flats in Europe with barrier islands and spits can be found from western Denmark all along the German North Sea coast and the

Europe, Coastal Geomorphology, Fig. 7

Satellite image of Sognefjord in western Norway, the deepest (more than 1,200 m) and longest fjord in northern Europe with about 200 km of length and a width of 1–8 km. Around the mouth of the fjord structural control of the coastline in very old crystalline rocks, worked out by several glaciations (© EOSAT, GAF, AAF 1985)

Netherlands to Belgium and northernmost France (Fig. 20). Furthermore, inland marshes are typical (Dijkema 1987), and along broader sandy beaches, coastal dunes are well developed (Baker et al. 1990; Clemmensen et al. 2009; Jackson and Cooper 2011). Other areas of tidal flats are present in many ria embayments from Ireland to Great Britain and western France. They partly are rocky, exhibiting a rich variety of algal belts and hard encrustations of barnacles, mussels, etc. Northern England shows a great variety of spits, marshes, tidal bays, bars (Fig. 21), forelands with wide beach ridge systems (Fig. 22), and uplifted coastal terraces, whereas the southern part is dominated by the world famous high chalk cliffs along the English Channel and rias of different length and steep rocky headlands to the southwest. The southwestern coast of France along the Bay of Biscay shows the longest coastal dune belts of Europe with shifting sands more than 100 m height (Fig. 23).

The coastline of Northern Spain along the Bay of Biscay is rocky with cliffs and caves cut into the limestone. To the west narrow and deep rias can be observed (Fig. 18), which change to the Portuguese coast into wider and shallower fluvial

embayments. The coasts of Portugal, however, are mostly sandy with dune belts and lagoons, except of some rocky headlands and the high and steep cliffs developed in the hard limestone at the southwestern most point of Europe. They are constituted of soft rocks with numerous small landslides at the south-facing Algarve coast. Continuing to the Strait of Gibraltar the eastern Portuguese coastline and the Spanish one are mostly low and bordered by lagoons and dune belts along sandy beaches. Only the last 50 km exhibit rocky coastlines, headlands, and cliffs with smaller sandy beaches.

The volcanic archipelagos of Madeira, the Azores, and the Canary Islands are mostly steep, some with megaciffs up to more than 500 m height. They are not singularly formed due to abrasion, but in addition they represent head scars of huge submarine slides from the collapse of the high and growing volcanic edifices.

The coastlines of the Mediterranean are limited in their coastal forms because tides are nearly absent, and longshore drift is less efficient because of the smaller ocean areas. Thus, the limited tides and wave energy conditions are responsible

Europe, Coastal Geomorphology, Fig. 8

Satellite image of northern Germany and southern Denmark. To the west tidal areas with different types of islands (Pleistocene morainic hills, younger Holocene marshes, very young spits and dunes), sandy bars, and muddy flats with tidal rivers and ebb deltas occur. To the east at the Baltic coastline ingressions into morainic and fluvioglacial relief on the Danish islands or into ria-like *förden* is typical in an environment without tides (© ESA, Eurimage 1992, GAF 1995)

for many deltas, among them the very large ones of Ebro (Fig. 24), Rhône, or Po (Fig. 25) and numerous others along the Italian and Albania coasts. Headlands with cliffs in limestone including bioerosive notches alternate with longer

beach sections at the Spanish Mediterranean coastline, whereas in southern France the western section consists of beaches, barriers, beach ridges plains, and the Rhône delta and of rocky steep coastlines in the east with calanques and

calas, which are dominant on the Balearic Islands, as well. The most extended granitic coastal landscapes decorated by huge boulders from deep weathering during pre-Pleistocene times and Holocene tafoni can be found around the islands of Corsica and Sardinia. Here, also longer sections of coastal barriers and lagoons exist. Except for the young volcanic Aeolian Islands, Italy has beaches along nearly 70% of its coastline, whereas in the southeast and on Sicily, cliffs and Pleistocene coastal terraces are widespread. From Istria to

northern Albania, drowned landscapes with typical parallel canale features occur (Fig. 3); beaches are very rare. Another type of an ingressive coastal landscape can be found along the Greek and Turkish coasts. It is the various change of structural embayments as grabens and horst-like long peninsulas (Figs. 2 and 5), mostly showing drowning as the predominant process with medium-to-steeper slopes but a less amount of real cliffs. Limited sections of uplifted coastal terraces alternate with beaches along barriers and deltas.

Europe, Coastal Geomorphology, Fig. 17 Forms and sediments along the coastlines of the European continent

Europe, Coastal Geomorphology, Fig. 18 Ria coast in NW Spain (Credit: Google Earth)

The islands of the Aegean Sea again are drowned remnants of an older land bridge (Fig. 10), sometimes with karst features (Fig. 11). Due to the absence of longer rivers and the rather dry climate, beach material is scarce. Neotectonics are an important process in coastal forming, as well as bioconstruction at the warmest easternmost parts of the Mediterranean, where many of the small beaches are cemented by Holocene beachrocks.

The maps do not show areas of artificial coastlines mostly due to the need for protection against storm floods in winter by groins, beach nourishment, sea walls, dikes, or land reclamation, most widespread around the North Sea as well as along Mediterranean bathing beaches and harbors.

Many of the European coasts are endangered (Caputo et al. 1991; Bartolini and Carobene 1996). The primary cause hereby is the accelerated erosion along beaches – at least 75% of all European beaches suffer from this process – marshes, and coastal dunes, which as a consequence costs billions of Euro/

year for maintaining bathing beaches, coastal settlements, or farmland. The reason is a small general sea-level rise and a local accelerated one caused by deltaic sedimentation, downwarping of a ring-like structure around the glacio-isostatic uplifted areas, or pumping of oil, gas, or groundwater from below the sea. Some of the reasons of the accelerated erosion may be located not directly along the coasts but far inland. The predominant cause is the increasing number of reservoirs holding back sediment and the mining of sand, gravel, and cobble from river beds, in particular, in the Mediterranean area. Consequently, millions of tons of sediment are not transported to the coasts any longer. This is in striking contrast to a period of progradation and delta buildup during late Holocene and historic times, in particular, during the Greek and Roman antiquity and early Medieval times, in some places even starting during the later Neolithic. For several 1,000 years progradation was in particular responsible for the development of barriers, spits, or marshes in spite of the still slowly rising sea level. The reason was the ongoing extension of agriculture and deforestation, resulting in soil erosion and denudational processes apart from the coast (see also Caputo et al. 1991; Simeoni and Corbau 2009; Labuz 2015). At many places, human impact on the coasts can be traced back in historic times, and geoarchaeology is used to identify changes of shorelines, sedimentation, and sea level (Behre 2001; Anthony et al. 2014; Peeters and Momber 2014). Coastal protection against the increased frequency of storms is another problem, which leads to the design of continuous new and higher dikes. It can be stated that overall the shape of some thousands of kilometers of coastline in Europe is the result of anthropogenic structures. However, beside that, heavy pollution due to tourist settlements or rivers bringing pulp mill sewage to the sea and oil spillage from heavy road traffic additionally are causing severe problems in coastal areas.

Pleistocene and Holocene Sea Levels

In northern Europe, glaciation has eliminated all traces of sea levels from former interglacial highstands, and those are mostly missing in areas without significant uplift like around the North Sea basin and the English Channel. In contrast evidences of higher interglacial sea levels as sediments with marine fossils (e.g., the foraminifera *Hyalinea balthica* for colder events in the older Pleistocene, or the tropical gastropod *Strombus bubonius* for the younger interglacials in the Mediterranean) or even as geomorphic features like coastal terraces are widespread in the geologic young environments of the alpidic orogenesis. Côte d'Azur between France and Italy, northern Sicily, or Apulia and Calabria in southern Italy are world famous sites for the discussion of higher interglacial sea levels. At some places, such as in SW and NE Peloponnesos, Greece, or southern Italy, terrace sequences reach several

Europe, Coastal Geomorphology, Fig. 25 Satellite image of the delta of River Po, Italy. Progradation mostly is a young Holocene feature (© ESA, Eurimage 1989, GAF 1989)

100 m above sea level. Unfortunately, the absolute dating determination remains still rather difficult. The coasts and the islands of the eastern Mediterranean exhibit remnants of higher sea levels but mostly in short sections, bordered by faults and areas of significant subsidence. The differentiation of substages within the same interglacial (like oxygen-isotopic stages 5e, 5c, 5a) is still under research. Nevertheless, the study of high (or uplifted) interglacial sea-level evidence has contributed greatly to the understanding of Mediterranean neotectonics.

Holocene sea level is a topic of intensive discussion in the scientific community. In northern Europe, a very good

dating of glacio-isostatic rebound by the analysis of uplifted beach ridge sequences exists (Fig. 22), whereas along the marshy German, Danish, Netherlands, and English coastlines of the North Sea, geo-archaeology has much contributed to the identifying of former Holocene sea levels (Behre 2001). Here, the sea-level curve of the last 6,000 years is characterized by at least two transgressions and regressions of 1–3 m. Some archaeological remains of the Bronze Age below high water level in the high tide range area of western France point to a sea-level rise of more than 3 m in this geologic stable region. Along the Mediterranean coastlines, archaeology as well contributes to the identification of the Holocene sea-level curve: drowned Phoenician harbors and ruins and quarries from Greek antique times, the position of Roman fish tanks, and even relics of early Christian periods can be found below sea level. Beside these man-made structures, natural sea-level indicators are very suitable for relative dating approaches, among them bioerosive notches (Fig. 9) or bioconstructive elements like trottoirs or algal and vermetid rims (Fig. 15 and Kelletat 1997). They are more reliable than beach ridge sequences, beachrock, or terraces along deltas. In spite of literally hundreds of dated and measured sites, there is no general agreement about the eustatic sea-level movements in the younger Holocene in the Mediterranean. But, nevertheless, these studies have led to a much better understanding of the ongoing and vivid neotectonics in this part of Europe, reaching a maximum of 9 m on western Crete (Greece) since the year AD 365 (Pirazzoli et al. 1996).

Conclusion

The complex contours of the European continent, its long shorelines, and its position between high Arctic to subtropical latitudes as well as per-humid to arid climates result in the presence of nearly all coastal forms and types of the world except of mangroves and coral reefs. Marine forming processes as waves and tides also show large variations. Beside anorganic factors, organic ones contribute to coastal forming additionally and in particular influence coastal ecosystems as in the macro-algae belts in the north, or bioerosive and bioconstructive indicators dominantly in the Mediterranean. As coastlines normally occur along a horizontal level, dislocations like uplift out of Holocene and interglacial levels as well as tilting are perfect indicators for the analysis of tectonic movements or those from glacio-isostatic rebound. Additionally, the long and well-documented history of human occupation and numerous archaeological remains in the coastal realm contribute to the differentiation of even small environmental changes along the coasts during the younger Holocene well into historical and modern times.

Eustasy

Vivien Gornitz
Columbia University/Center for Climate Systems Research (CCSR), Earth Institute Affiliate: Columbia University/
Goddard Institute for Space Studies (GISS), New York,
NY, USA

Definition

Eustasy originally referred to a globally simultaneous and uniform change in sea level. However, sea-level changes are affected by many processes that operate on different temporal and spatial scales. These processes are described more fully

Eustasy, Table 1 Summary of processes affecting global sea level

Process	Time scale (year)	Magnitude (m)
Changes in volume of ocean water		
Expansion/contraction of ice sheets (glacial eustasy)	10^4 – 10^5	120–140
Expansion/contraction of mountain glaciers	10 – 10^4	0.5
Changes in ocean temperature/salinity (steric changes)	10 – 10^4	10
Changes in ocean basin volume		
Plate tectonics and mountain uplift	10^7 – 10^8	100–500
Sedimentation (continental shelves)	10 – 10^8	100
Glacio-isostasy	10^4 – 10^5	100–500
Hydro-isostasy	10^4 – 10^5	30–40
Local sea-level changes		
Sediment loading and compaction (river deltas)	10–1000	<1–20
Localized faulting and tectonic deformation	1–1000	<1–3
Land subsidence (subsurface fluid extraction)	10–100	<1–2
Oceanographic and atmospheric variability	<1–10	<1–10

After Gornitz (2013) and sources cited therein

below and summarized in Table 1. Therefore, the original concept of eustasy, as a globally uniform rise in sea level, has been challenged, and some authors suggest abandoning the term altogether (e.g., Carlson and Clark 2012). Nevertheless, eustatic sea level plays an important role within the framework of geophysical models that calculate glacial isostasy (see below; Peltier 2004; Mitrovica et al. 2010; Lambeck et al. 2010; Spada 2017). In current usage, the eustatic sea-level change is the global sea-level change averaged over the surface of the oceans, over a specified time interval (Spada 2017).

Suess (1888) originally attributed eustasy to crustal subsidence and sediment deposition. Removal or addition of water to oceans during glacial-interglacial cycles was another proposed cause. Fairbridge (1961) summarized these theories as follows: (1) *tectono-eustasy* (tectonic deformation of the ocean basins), (2) *sedimento-eustasy* (loading of crust by sediments), and (3) *glacio-eustasy* (removal/addition of water to the oceans by expansion or contraction of polar ice sheets). Another process is *hydro-isostatic* loading of the seafloor by glacial meltwater (Walcott 1972; Clark et al. 1978; Mitrovica and Milne 2002).

Mean global sea level can change in two fundamentally different ways – the first by altering the mass (or volume) of ocean water and the second by varying the volume of the ocean basins. In the first case, the mass (or volume) of the contained liquid (i.e., ocean water) varies; in the second, the shape and dimensions of the container (i.e., the ocean basins)

are modified. The land-to-sea transfer of ice mass, and vice versa, during glacial-interglacial cycles represents the primary means of changing the amount of water in the ocean and, hence, global sea level (i.e., glacio-eustasy) (Table 1). These changes operate on timescales ranging between 10,000 and 100,000 years. However, changes in ocean temperature or salinity (i.e., steric changes) also affect water density, ocean volume, and hence water level, over much shorter timescales. On the other hand, changes in ocean basin volume caused by plate tectonics and mountain building span periods of tens to hundreds of millions of years. Loading or unloading of ice mass also alters basin shape (i.e., glacio-isostasy).

Seismic reflection profiles on continental shelves, collected during petroleum exploration in the 1970s, showed similar patterns of “sequence boundaries,” or regional unconformities, in passive margin sedimentary deposits from many parts of the world (see “► Sequence Stratigraphy”). Sequence boundaries have been widely interpreted as marking major episodes of synchronous eustatic sea-level falls, which are summarized in global sea-level curves (e.g., Vail et al. 1977; Haq et al. 1987). Although widely used, these curves have been criticized on grounds that sequence boundaries are uncritically accepted as eustatic, that magnitudes of sea-level fluctuations are largely speculative, and that boundaries have not been accurately dated (for good overviews, see Christie-Blick et al. 1990; Miall 1997). However, curves from various sources show certain common features, suggesting that at least some of these proposed sea-level events could be worldwide in scope. More recently, Miller et al. (2005, 2011) have developed a eustatic sea-level curve that combines marine oxygen isotope data with continental margin and seismic stratigraphy, corrected for effects of basin subsidence, sediment compaction, and loading.

Causes of Eustasy

Sea level integrates the effects of diverse geological and meteorological phenomena, such as glacio-eustasy, glacio-isostasy, plate motions, etc., which operate on differing spatial and temporal scales (Table 1). The relative magnitudes of these processes vary from place to place, thus tending to obscure any globally coherent sea-level signal. As a result, the search for a universal “eustatic” sea-level curve has turned toward obtaining improved regional and local (“relative”) sea-level curves (Lambeck et al. 2010). Yet, as shown below, improved modeling of glacio-isostatic adjustments and detailed, accurately dated sea-level data from areas of known uplift enable reconstruction of global sea-level rise over the last 18,000 years and the past century. Processes affecting global sea level over various geologic timescales fall into three main classes (Table 1). These involve (1) changes in the volume or mass of ocean water, (2) changes

in the volume of the ocean basins, and (3) dynamic changes of the ocean surface.

Changes in the Volume or Mass of Ocean Water

Glacio-eustasy. Melting or accumulation of continental ice sheets during the last 2.7 million years has produced large changes in ocean water volume and global sea level. These oscillations of sea level over timescales of tens to hundreds of thousands of years are caused primarily by changes in solar radiation arising from periodic variations in the earth's orbit around the Sun (the “Milankovitch” cycles, Imbrie et al. 1984).

Changes in sea level during glacial-interglacial cycles have been estimated from fluctuations in the ratio of ^{18}O to ^{16}O in deep-sea microorganisms, such as foraminifera from ocean sediment cores, and also by dating emerged coral reefs on tectonically rising islands (see “► [Geochronology](#), ► [Coral Reefs](#), ► [Coral Reef Coasts](#), ► [Coral Reefs, Emerged](#)”). Variations in the oxygen isotope ratio serve as a proxy for alternations in global ocean volume, and hence in sea-level, linked to changing masses of continental ice. Sea-level curves for the past several hundred thousand years have been constructed from well-dated raised coral terraces on Barbados and Papua New Guinea (Lambeck et al. 2002; Siddall et al. 2007). These data show highstands of sea level at approximately 193,000, 125,000, 100,000, and 83,000 years ago.

The post-glacial marine transgression of the last 19,000 years has been plotted by careful radiometric dating (^{14}C and ^{230}Th - ^{234}U) of corals from three widely separated oceanic islands with known tectonic trends and minimal glacio-isostatic influence and various other localities. A compilation of data from these sources yields a generalized sea-level curve that shows a remarkably consistent and uniform rise of around 120–130 m, which therefore represents a eustatic curve for the last deglaciation (Fig. 1, after Gornitz 2013, Table 5.1, and sources cited therein; Peltier and Fairbanks 2006; Carlson and Clark 2012; Deschamps et al. 2012; Liu et al. 2016). However, several periods of accelerated sea-level rise (termed “meltwater pulses”) are detected: the oldest at around 19,000 years BP (labeled MWP-1A₀), followed by the largest upward sea-level jump, 16 m in ~350 years (meltwater pulse 1A, MWP-1A), during the relatively mild Bølling-Allerød period between 14,600 and 14,000 years ago (Deschamps et al. 2012; Fig. 1). This episode was later succeeded by two weaker meltwater pulses (MWP-1B and MWP-1C, respectively, Fig. 1). Meltwater pulse 1B – between 11,500 and 11,000 years ago – occurred after a return to warmth, following the Younger Dryas cold period between 12,800 and 11,700 years ago. Although fossil corals from Barbados record this sea-level jump, elsewhere this event appears only as a slight acceleration in the overall

Eustasy, Fig. 1 Generalized sea-level curve of the postglacial marine transgression (Based on data in Table 5.1, Gornitz 2013)

trend of rising sea level (Bard et al. 2010). Meltwater pulse (MWP1-C) may be related to an episode, around 8200 years ago, when colder temperatures gripped Greenland and Europe. The cold may have been triggered by the final catastrophic drainage of giant remnant glacial lakes along the southern edge of the Laurentide Ice Sheet and discharge into Hudson Bay (Carlson and Clark 2012). Thus, meltwater pulse events generally correspond to major periods of rapid breakup and melting of the ice sheets (Fig. 1).

The process of glacio-eustasy is now well established for the late Cenozoic. Antarctica has been glaciated for at least 14 million and probably as much as 34 million years (Galeotti et al. 2016). The late Paleozoic Gondwana glaciation led to a major marine regression. A late Ordovician glaciation was centered on the Sahara Desert in North Africa. Beyond these, other glacial episodes are less well established.

Evidence for Milankovitch cycles in the geologic record extends possibly as far back as early Mesozoic (Olsen and Whiteside 2009). Additional indications of climate (and sea-level) variability associated with orbitally driven cycles also appear in Eocene-Oligocene boundary offshore marine sediments from the western Ross Sea, Antarctica (Galeotti et al. 2016), and in Pliocene glaciomarine deposits from the Ross embayment (Naish et al. 2009). A transitional period, roughly 1.2–0.9 million years ago, marked the onset of at least eight major glacial-interglacial cycles that lasted roughly 100,000 years, each. Prior to the mid-Pleistocene transition, older orbital cycles were largely dominated by 41,000-year obliquity cycles. Reasons for the changeover from late

Pliocene-early Quaternary obliquity-dominated cycles to 100,000-year eccentricity-driven cycles within the last millennium years remain unexplained.

Hydro-eustasy: Redistribution of water among the major terrestrial hydrological reservoirs, in response to major climate shifts, can also affect the ocean's level. A potentially significant terrestrial reservoir on timescales of tens to hundreds of thousands of years resides in groundwater (Hay and Leslie 1990). Sediments may contain enough pore space to hold the equivalent of 76 m of sea level (or 50 m with isostatic adjustment).

Steric changes: Over timescales of decades to centuries, changes in ocean water density become important contributors to sea-level change. Warming, cooling, or changes in salinity of ocean water affect its volume (but not its mass content). Thermal expansion of the upper layers of the oceans, as the earth's climate warmed approximately 0.85 °C during the last hundred years, could account for 0.1–0.7 mm/year of the observed sea-level rise of 1.5–1.9 mm/year during this period (Church et al. 2013). The thermal expansion of ~1.1 mm/year between 1993 and 2010 represents about a third of the observed recent sea-level rise of 3.2 mm/year.

Changes in Volume of Ocean Basins

Tectono-eustasy: On geologic timescales of tens to hundreds of millions of years, major factors controlling sea level include changes in seafloor spreading rates, cooling of oceanic crust, and passive margin thermotectonic subsidence (Rona 1995; Miller et al. 2005, 2011). At times of rapid seafloor spreading, a comparatively larger volume of younger, warmer, more buoyant basaltic crust is created at mid-oceanic ridges. This displaces water, raising sea level on the continental margins. Slow seafloor spreading rates produce the opposite effect. Plate collision, thrusting, and terrane accretion can also cause changes in sea level on timescales of 10^7 years. Continental collision reduces land area due to compression, producing a corresponding increase in ocean area which can lead to a drop in sea level of up to 100 m (Table 1). Other tectono-eustatic mechanisms include hot-spot activity and deep mantle upwelling (Hallam 1992).

Sedimento-eustasy: Displacement of water by sedimentation on continental margins and ocean basins displaces water, causing an apparent rise in sea level.

Glacio-isostasy: Loading and unloading of ice masses during major glacial cycles induce nonuniform glacio-isostatic adjustments of the earth's crust (Table 1). Resulting changes in coastal elevation strongly affect the location of the earth's coastlines and local sea level. For example, much of Canada and Scandinavia, formerly covered by ice, are still rebounding isostatically, and local sea level is falling. Conversely, eastern United States and the low countries of

Europe, at the southern edge of the ice, are still subsiding, with locally rising sea level (Peltier 2004; Engelhart et al. 2011). GIA-related subsidence accounts for a third to half of the observed recent sea-level rise along the US east coast (Engelhart et al. 2011; Engelhart and Horton 2012).

Geophysical models (GIA or glacial isostatic adjustment models) calculate the redistribution of mass accompanying the last deglaciation, as well as that associated with recent global warming (Peltier 2004; Mitrovica et al. 2010; Lambeck et al. 2010; Peltier et al. 2015; Spada 2017). These models filter out residual glacio-isostatic movements which contaminate the twentieth century sea-level records based on tide gauges. This has allowed an estimation of the climate warming-induced “absolute” or eustatic sea-level change (e.g., Church et al. 2013; Jevrejeva et al. 2014). An alternative approach employs paleo sea-level proxies, such as tidal zone fossil microfauna, plants, and well-dated basal peat samples, to calibrate and constrain GIA models and to reconstruct paleo sea-level history (e.g., Engelhart et al. 2011; Engelhart and Horton 2012; Gehrels and Woodworth 2013). Recent GIA models also include rapid melting of large ice reservoirs which changes the gravitational pull between the shrinking ice mass and surrounding ocean, the Earth's rotation, as well as the instantaneous (elastic) component of the glacial isostatic response. The changing mass of each major ice sheet or large glacier would result in a geographically distinct pattern of sea-level change, referred to as a “sea-level fingerprint” (Mitrovica et al. 2010, 2011; Spada 2017). In turn, the geographically variable sea-level trend can help pinpoint the meltwater source.

Dynamic Changes

Atmospheric and oceanographic processes are responsible for fluctuations in sea level that last from 1 to 2 years to a decade or more and are coherent over long distances. These fluctuations arise from ocean currents and closely coupled oceanographic-atmospheric phenomena, such as the Northern Atlantic Oscillation (NAO) or the El Niño–Southern Oscillation (ENSO) in the Pacific Ocean (see “► [El Niño–Southern Oscillation \(ENSO\)](#)”; Table 1). During the El Niño phase of the ENSO cycle, anomalously warm water propagates eastward, splitting into north and south poleward-propagating Kelvin waves, causing sea level to rise (for several months) along the west coasts of the Americas (Tingstad and Smith 2007). During the positive phase of the NAO cycle, the pressure gradient between the Icelandic Low and the Azores High intensifies, strengthening prevailing westerly winds across the North Atlantic. Storm tracks move farther north-east than usual; Great Britain and Scandinavia experience milder but stormier than average winters. Higher storm surges generated by the strong westerlies combine with

reduced atmospheric pressure and above-average sea surface temperatures to raise regional sea level during the event (Woodworth et al. 2007). These fairly short-lived dynamic ocean fluctuations generally do not lead to permanent change in average ocean height. Yet, their effects on the coastal zone and its inhabitants, superimposed on a rising global sea level, can have profound consequences (see “► Natural Hazards”).

Conclusions

Sea-level change is a complex phenomenon, varying considerably over space and time. Nonetheless, considerable progress has been made in modeling of glacio-isostasy and in accurate dating of Holocene sea-level proxies. This information will enable a clearer separation of the present-day eustatic (global) sea-level signal from regional to local geophysical and oceanographic factors.

Eustasy and Sea Level

Ervin G. Otvos

Division of Coastal Sciences, University of Southern Mississippi, Ocean Springs, MS, USA

Original and Modern Definitions of Eustasy

The concept of eustasy has been defined as the global (or “absolute”) sea level and/or synchronous uniform worldwide changes in mean sea level (Neuendorf et al. 2005). Considering marine regressions during glaciations and interglacial transgressions, Suess (1888) introduced this Greek term for “well fixed,” or “static,” referring to the assumed globally synchronous water levels in the world ocean with implied permanent and rigid basin walls and floor. This concept emerged decades before the very existence, let alone knowledge of the viscous-elastic nature of the mantle-crust system became known. Solid Earth deformation and associated plate tectonic processes are the essential features of eustatic phenomena (Rovere et al. 2016b). The complex interrelationship between the viscous-elastic crust-mantle complex, fluctuating ocean levels, basin dimensions, and the gravitational and rotational influence of the variable ice and water loads on the crust are key aspects of eustasy.

Eustatic (ESL) and Relative Sea Level (RSL)

Eustasy in the current definition essentially involves fluctuations that take place in water volumes located within and on

the crust of the Earth. The term eustasy in contemporary thinking corresponds to mean global sea level without the impact of local factors. The concept refers to the position of the sea surface as related to a fixed datum, such as the center of the earth or a satellite in fixed orbit around the earth. However, because this position varies due to various “eustatic changes,” a somewhat inconsistent term, it is impossible to determine the size of past variations in the eustatic position of sea level (Burton et al. 1987). Constant changes in the uneven topographic and bathymetric configurations of the ocean basins lead to continuous changes in the shapes and dimensions of these basins. Any observed and measured sea level alteration related to a land-based reference frame, i.e., uplift and subsidence of land masses, is defined as a relative RSL change that modifies eustatic, global sea level positions (Rovere et al. 2016b). Changes are due to vertical displacement of the global ocean surface and of the surrounding land masses as well as additional factors. Movements occur either in the same or opposite direction. In the general literature, however, the term “eustatic change” often is limited to ice-equivalency-related glacial and deglacial fluctuations in the level of the World Ocean.

Global and Local Sea-Level Changes

As opposed to the theoretically conceived eustatic global mean sea level (ESL), “eustatic fluctuations” thus are not worldwide and uniform in extent. The mechanisms of changes that operate over local and spatial scales during specific time intervals are not considered eustatic. They result from temporal and local changes in water volumes in the world ocean and in mean global sea level (Gornitz 2005, Miller et al. 2005). A purely eustatic signal can not be observed in isolation-eustatic sea level therefore is not a “tangible” physical entity with a spatial scale. Satellite technology will establish quantitative global changes in the future. At present, the eustatic signal still provides a reference value regarding the unscaled global eustatic mean sea level. Eustatic sea level thus may be regarded as a general climate change index in terms of melting and freezing ice cover, as well as oceanic temperature and salinity variations. It is also modified by changes that occur during other temporal processes related to variations in ocean level, water volume, water mass, as well as other factors. The following changes, often described as “eustatic,” are prime modifiers of unscaled global mean sea levels (Rovere et al. 2016b).

“Eustatic fluctuations” are caused primarily by water volume changes in the world ocean and in mean sea level (Gornitz 2005; Miller et al. 2005), as well as by changes that occur during other temporal processes related to variations in ocean level, water volume, and water mass. The following

factors contribute to major sea level changes, often designated as “eustatic”:

1. *Glacio-eustatic changes* occur by the accumulation or disintegration of global ice sheets. They denote melting and growth of continental ice volumes over time (Daly 1934; Peltier 1999; Lambeck et al. 2012). Periodic massive meltwater flow from thawing continental ice sheets and glaciers played a singular role during the numerous Quaternary eustatic sea-level rise events.
2. *Hydro-eustatic changes* (Hay and Leslie 1990; Gornitz 2005; Khan et al. 2015) refer to water redistribution between different global reservoirs in the form of snow, surface water, soil moisture, and ground water. The changes do not include the continental glacial meltwater effects.
3. *Thermosteric and halosteric density changes*; water volume contraction or expansion result from changes in temperature and salinity, respectively, due to ocean water cooling or warming and salinity increases or decreases (Gornitz 2005; Rovere et al. 2016).
4. *Tectonic eustatic changes* refer to long-term, mostly tectonics-related ocean basin volume reduction by ocean water displacement during magma and lava intrusion or an increase in basin capacity due to newly created accommodation space. These processes involved slow and fast rates of sea-floor spreading, mid-ocean ridge formation, and plate subduction, including ocean trench development (Rona 1995; Leonard et al 2004; Miller et al. 2005).
5. *Sediment eustasy*. Displacement of water by accumulation of large sediment volumes on the seafloor along continental margins and in ocean basins also raises the ocean level (Gornitz 2005).
6. *Geoidal eustasy, continental ice cover, and gravity anomaly changes*. Geoidal eustasy refers to ocean level changes caused by altered global distribution of ocean water due to geodetic changes in ocean level (Mörner 1976; Mitrovica and Peltier 1991). Planet Earth is broadly flattened at the poles, bulging at the equator, and the ocean surface does not parallel the Earth surface. The elevation of this “geodetic sea level,” with respect to the distance to the center of the Earth, varies by as much as 180 m. While the continental crust underwent viscoelastic rebound due to deglaciation, the low-latitude gravity anomaly that evolved during the preceding peak glacial stage had vanished. Its disappearance drove water masses of the oceanic geoid to migrate from lower to higher Earth latitudes. Consequent sea level changes in the last four millennia involved the north Atlantic region during the current Late Holocene highstand. Low-latitude oceanic islands, such as the Cocos (Keeling) Islands, experienced concurrent RSL decline, the emergence of marginal new land areas from the eastern Indian Ocean (Woodroffe and McLean 1990; Table 1).

Eustasy and Sea Level, Table 1 Summary of processes affecting global sea level (Gornitz 2005, p. 440)

Process	Rate (m/ka)	Duration (year)	Amplitude (m)	References
Change in ocean water quantity				
Glacio-eustasy	10	10^4 – 10^5	120–150	Bard et al. (1996); Fairbanks (1989)
Hydro-eustasy	0.5–5	10^4 – 10^5	~50	Hay and Leslie (1990)
Steric changes	I	10 – 10^4	10	Rona (1995)
Change in ocean basin volume

Relative Sea-Level Change Factors

The interplay between eustatic sea level and factors that determine RSL triggers relative sea-level changes (Figure 1). While uplift or subsidence do take place in the adjacent land areas, the volume and mass of ocean water bodies remain unchanged. Interaction between eustatic and relative sea-level changes create a variety of geomorphic markers that are critical in the evaluation of relative sea-level changes, as well as the local transgression and regression history in a given coastal region (Baker et al. 2001; Miller et al. 2005). Direct and indirect markers include marine notches carved in bedrocks, erosional and aggradational marine coastal terraces, submerged and emerged coral reefs and other shallow subtidal fauna and flora elements, interface between sand units with subtidal-intertidal and supratidal (eolian) sedimentary signatures, and others (*q.v.*, ► [Gulf Shorelines, Last Eustatic Cycle](#) – Encyl. Chapter by Otvos).

Glacio-Isostatic Adjustment (GIA) and Hydro-Isostatic (Added/Reduced Water Load) Effects

These processes occur before, during, and following ice sheet establishment and melting. GIA is defined as the “viscoelastic response of the Earth to the redistribution of ice and ocean loads” (Dragert et al. 1994; Peltier 1999; Woodroffe and Horton 2005; Lambeck et al. 2012). Depending on the different stages of the process, these factors are related to ice

Eustasy and Sea Level, Fig. 1 Sea-level curve of the post-glacial marine transgression. Based on radiocarbon and U-Th dating of corals from Tahiti, Barbados, and New-Guinea (Gornitz 2005, modified from Bard et al. 1996)

loading, as well as melt water loading and unloading. Ice sheet growth results in subsidence beneath continental ice masses. Responding to loading, viscous mantle matter flows away from ice-loaded regions and creates an uplifting peripheral bulge in the “near-field” of the ice margin (Daly 1934). Mantle flow starts under loaded crustal areas and creates an uplifting peripheral forebulge in the “near field,” close to formerly glaciated regions. Even in remote “far-field” regions, at great distances from glaciation centers, water removal from the ocean results in crustal uplift due to reduced hydrostatic pressure by overlying waters. During and following crust relaxation, “unloading,” as melting disposes of the continental ice sheets, the flow direction of the viscous mantle matter reverses toward the formerly ice-loaded site. The peripheral forebulge decays. Forebulge subsidence controls sea-level changes even in “far-field” equatorial areas (Khan et al. 2015). Crustal unloading results in isostatic uplift at rates that may reach 5–10 cm/year. Ocean waters fill bathymetric lows as they gradually develop in the process of forebulge collapse. This “equatorial ocean siphoning” effect (Mitrovica and Peltier 1991) led to RSL decline and the consequent Mid-to-Late Holocene highstands of Pacific islands (Woodroffe and Horton 2005; Rovere et al. 2016a, b).

Differences in the width of continental shelf and in its impact on hydro-isostatic adjustment during the Late Holocene caused a differential crustal flexure under Australia’s eastern coastal region. This has also defined the Mid-Holocene time of the marine highstand in the area (Flood and Frankel 1989; Baker et al. 2001). “Continental levering” occurs in the final stage of post-glacial sea-level rise along the

continental margins in far-field areas. Upward tilt of continental coastal sectors takes place in response to increasing water load in ocean basins. The seafloor subsides and the viscous upper mantle matter is pushed toward the continents. At the same time, due to lithosphere flexing, coastal areas may experience local uplift with consequent RSL decline (Woodroffe and Horton 2005).

Rapid ice sheet melting that leads to sea-level decline within a few thousand kilometers of the ice sheet and a progressively increasing rise in sea level at greater distance in tandem effects of crustal rebound, involves changes in gravitation attraction as well. The largely elastic deformation involves diminution of the gravitational pull that melting ice sheets exercise on the ocean waters. Rotational effects of Earth do also contribute to the process (Milne and Mitrovica 1998; Creveling et al. 2015). When an ice sheet grows, the mutual gravitational pull attracts water masses. When the ice sheet melts, the pulling forces on the water decrease, with a net effect of RSL fall in the near field and an RSL rise in the far field (Woodroffe and Horton 2005; Rovere et al. 2016a and other sources).

Additional RSL changes and their causes (Lambeck and Nakada 1990; Gornitz 2005; Woodroffe and Horton 2005; Rovere et al. 2016a, b; Rona 1995) are as follows:

1. **Interseismic land uplift and coseismic land subsidence** along subduction zones due to divergent and convergent mantle current flow, respectively.
2. **Volcanic isostasy** caused by increased volcanic loading on the crust. Current flow within mantle displaces matter away from loaded sites.
3. **Sediment compaction**-related seafloor subsidence increases accommodation space to be occupied by ocean water. This occurs particularly in marginal ocean areas underlain by a thick sequence of unconsolidated deposits (e.g., Mississippi and Nile deltas). Sediment redistribution, erosion from land, and redeposition in ocean do not change the ESL either.
4. **Karst solution-unloading phenomena.** Loss by karst terrain reduction and lowering, cavity formation and collapse influence RSL by dissolution and consequent compaction processes (Rovere et al. 2016b).

Interaction between eustasy and local RSL forcing factors – examples (q.v., Encyclopedia Articles, ► Modes and Patterns of Shoreline Change, ► Gulf Shorelines, Last Eustatic Cycle Chapters)

Specific Examples of Sea Level Fluctuations

Combined eustatic and RSL factors were responsible for the multimillennial time lag between the start of the Holocene

highstand in the Indo-Pacific realm and the North Atlantic region. By 5–6 ka B.P. when the RSL of the Gulf of Mexico stood at ~ -4 m, Pacific mean sea level reached +2–3 m at various Australian and Pacific island sites (Pan et al. 2018; Otvos, Last Interglacial chapter, present volume). Recorded low sea levels during the Glacial Maximum, 18 ka B.P., appear at various depths below present sea level. These depth figures differed between various locations by as much as 30 m (Nakada and Lambeck 1989; Lambeck and Nakada 1990; Woodroffe and Horton 2005). Isostatic and other RSL-related factors have resulted in the uplift of Late Pleistocene (MIS 5c Substage) US Atlantic coast terraces from intermediate to Last Interglacial (LIG) record elevations (e.g., Wehmiller et al. 2004; Rovere et al. 2016a). Anomalously high (+6 to +9 m) Late Pleistocene LIG sea-level markers in areas generally considered tectonically stable in South Florida, South Africa, the granitic Seychelles Islands “mini-continent” in the western Indian Ocean, and parts of Australia (e.g., Flood and Frankel 1989; Baker et al. 2001; Muhs et al. 2011; Creveling et al. 2015) are yet to be adequately explained by eustatic RSL models. These sites may have been affected by local mantle current upwelling.

Dynamic changes (Table EB) are causing short-term fluctuations in sea level due to coupled ocean-atmosphere variations. They include El Niño, La Niña, ENSO, SOI, AMO (Atlantic Multidecadal Oscillation), NAO (North Atlantic Oscillation), and several other global and regional oceanographic-weather cycles (Gornitz 2005, and others). An indirect impact by increased or decreased precipitation over ocean basins also influences ESL (Rovere et al. 2016). (q.v., Encyclopedia Articles: *Last Interglacial*; *Barrier Island Formation and Development*).

Summary

Eustasy relates to global water volume and mass changes in the world's ocean driven by a variety of processes, primarily glacio- and hydroeustatic in nature. Isostatic effects, manifested among others, by peripheral forebulges created by continental ice load, as well as their decay effect near, intermediate, and far-field settings. They are linked to regional uplift and subsidence processes. Isostasy, combined with other factors, helps to explain major differences between Quaternary sea-level curves established in various regions on the planet. Glacial isostatic adjustment, a major RSL component makes the observed local sea level change different from a theoretically established global mean sea level (eustatic) value. The record observed at any given field site is related to RSL change. Its value differs from the mean global eustatic value. At the same time, somewhat inconsistently, the change itself is attributed to the mechanism of “glacio eustasy”. In addition to isostatic processes equatorial ocean siphoning,

changes in ice-sheet related gravitational anomalies, and releveling do also influence relative sea level positions and their changes. Lithospheric plate subduction, oceanic seafloor spreading, mid-oceanic ridge, and deep oceanic trench formation, potentially also mantle current up- and downwelling are among the most important, long- and very long-term tectonic influences that impact ocean basins and global eustatic changes. “Eustatic” changes, most validly defined, are already monitored by the new global satellite altimetry.

Faulted Coasts

Roland P. Paskoff
Lumiere University, Le Chesnay, France

Faulted coasts are chiefly associated with active continental margins where tectonic plates are colliding. They often correspond to bold coasts, characterized by continuously steep and straight scarps. However, terraced coastal areas dislocated by faults as well as fiord or estuary coasts controlled by faults have also to be included into the broad category of faulted coasts.

Sea Cliffs and Fault Scarps

In some instances, coastal cliffs may be identified as fault scarps of direct tectonic origin which separate raised blocks of land from dropped ones that have been depressed below sea level. Plunging cliffs, cliffs which are not fronted by shore platforms or beaches and plunge abruptly into deep water, can be the product of recent faulting if down-thrown blocks have subsided to appreciable depths. In that case, and not only in sheltered waters and even if the resistance of rocks is not considerable, plunging conditions could persist long after faulting and the initial profile of the coast may long remain practically unaltered (Johnson 1919). Cliff recession is very slow since erosional processes are inhibited by the reflection of incoming nonbreaking waves against vertical or nearly vertical walls rising out of deep water. Furthermore, deep waters at the cliff base prevent accumulation of sediment derived from alongshore transport or subaerial scarp weathering, resulting in the lack of abrasive materials which could increase the erosive power of the waves. However, in the course of time, hydrostatic pressure and hydraulic

quarrying caused by the rise and fall of standing waves, and the compression of air in rock fractures eventually are able to produce notches and caves. Narrow erosional platforms may subsequently develop, allowing breaking waves to attack the cliff and destroy the plunging condition (Trenhaile 1987).

Several coastal cliffs in New Zealand are thought to be actual fault scarps (Cotton 1916). For instance, the cliffs along the Wellington fault, on the northwestern shore of Port Nicholson have been explained in this way. They slope at about 55°, show little evidence of marine modification at the shore level, and descend to a depth of about 20 m, close and parallel to the shoreline. In Russia, on the Murmansk coast, to the west of the White Sea, Archean granites and gneisses are faulted along a line which almost coincide with the present coastline. The foot of the cliffs extends to a depth of several tens of meters without alteration of slope. During storms, waves are reflected from the scarp wall and there are no wave-cut notches or fragments of benches (Zenkovich 1967). In the United States, some steep cliffs along the coast of California are attributable to fault scarps. For example, a down-thrown block has dropped below sea level on the northeastern side of San Clemente Island, forming a straight cliff with no intervening shelving bottom (Shepard and Wanless 1971). The Gulf of California, Mexico, gives nice examples of recent faulted coastlines, especially in the islands next to its western side where straight, continuous, and precipitous escarpments display faceted spurs and truncated structures, are not bordered by shelves, have deep water at their base, and show angular contact with the adjacent submarine basin (Shepard 1950). All these features are evidence of no marine erosion after faulting that is probably recent. For instance, the sea cliff on the southwestern side of Angel de la Guarda Island corresponds to a fault scarp which steeply plunges to the bottom of a trench located at a depth of about 1,000 m. In volcanic areas, cliffs can be directly produced by faulting induced by vulcanicity. Sea cliffs devoid of a bordering shelf on the southern flank of Kilauea Volcano, in Hawaii, can be identified as

direct normal fault scarps although, at least in some cases, they may correspond to gigantic slump scarps.

Sea Cliffs and Fault-Line Scarps

Most tectonically controlled coastal cliffs correspond to fault-line scarps that are scarps produced by structurally induced erosion at ancient faults. As a matter of fact, on the one hand there has been little time for important faulting since the post-glacial rise of sea level, on the other hand older original tectonic features are not retained for long because of the erosional effects of subaerial geomorphic processes during periods of low sea level. For example, along the steep Santa Lucia Mountain coast of central California, the continental shelf is in some parts less than 0.6 km wide, suggesting that this is a fault-line coast since a retreat of a relatively short distance, due to marine erosion, has followed faulting. In Japan, the straight mountainous coastline which characterizes the northwestern part of Shikoku stretches along the so-called Median Tectonic Line. In the Malta archipelago, the coastline pattern of the main island is mainly controlled by faulting. Here, in the northern part, bays correspond to downthrown blocks that were partially submerged. In the southwestern part, spectacular cliffs which can be more than 200 m high are erosionally derived from a major northwest trending fault, known as the Maghlaq fault that has been displaced vertically by at least 230 m and probably moved during the Quaternary (Paskoff and Sanlaville 1978).

In northernmost Chile, where the oceanic Nazca plate is subducted under the continental South American plate, the extremely arid coast is characterized, over more than 800 km, by a striking, precipitous, northward trending cliff which is 700 m high on average. Because of its length and height, this scarp represents a major geomorphic feature at a worldwide scale. From Arica (18°S lat.) to Iquique (20°S lat.) the cliff is almost vertical and its top can reach 1,000 m above sea-level. At present, it is an active feature, dropping into the sea and receding under marine action. As a result, ephemeral streams of wadi type are cut by the scarp and hanging above sea level (Fig. 1a). Landslides, triggered by earthquake shocks and affecting rock masses previously loosened by intense tectonic fracturation, are also contributing to the cliff retreat. From Iquique down to 27°S lat., the cliff remains very high but not so steep. As a matter of fact, it is no longer an active one since a belt of emerged wave-cut platforms, several hundred meters wide, extends at its base, indicating a relative fall in sea level (Figs. 1b and 2). The cliff of northernmost Chile is a typical fault-line scarp (Paskoff 1978). Detailed geological mapping failed to reveal faulting at the foot of the cliff whose lack of straightness is also inconsistent with a direct tectonic origin. Actually, the cliff results from an important faulting phase which generated major, north-south trending, *en*

échelons, normal faults at the end of the Oligocene Epoch and uplifted the continental block which constitutes the present Coastal Cordillera. Subsequently, these faults retreated under marine erosion, over about 10 km which is here the width of the continental shelf, mainly during a major middle to upper Miocene transgression. Later differential crustal movements occurred.

This explains why the cliff is an active one in its northern part where subsidence may be related to a collapse of the continental margin toward the Chile-Peru trench, and an abandoned one in its southern part where, on the contrary, an uplift motion has been taking place.

Faulted Coasts, Fig. 3 Geomorphological sketch of the southern part of the Talinay Heights coastal area in northcentral Chile (modified from Ota et al. 1995). (1) Talinay I wave-cut terrace (Pliocene?), (2) Talinay II wave-cut terrace, (3) Talinay III wave-cut terrace (oxygen isotopic stage 9?), (4) Talinay IV wave-cut terrace (oxygen isotopic stage 5), (5) dunes, (6) Quaternary fault

Coastal Terraces and Faulting

Former wave-cut platforms that have become emerged because of a fall of sea level due to some combination of eustatic and crustal processes are not unusual on coastal belts. When located on active margins, these elevated marine terraces generally show evidence of active faulting which has occurred in Quaternary time (Pirazzoli 1994).

In north-central Chile, the 110-km-long coast of the Talinay Heights area, between 30°S and 31°S lat., is characterized by a flight of several emerged Plio-Quaternary marine terraces which has been densely and strongly faulted, uplifted, and tilted (Ota et al. 1995). Dip-slip normal faults, which are early Pleistocene in age, have a clear topographic expression, forming conspicuous scarps. The most significant one is the Quebrada del Teniente fault (Fig. 3). Distinctively straight, NNW–SSE trending, it runs parallel to the present shoreline and crosses the entire area over a length of about 60 km, dislocating the terraces and generating a striking

east-facing scarp. The maximum amount of vertical displacement reaches 52 m.

In eastern Tunisia, the Monastir surroundings (36°N lat.) are wellknown for their Tyrrhenian (name used in the Mediterranean for the last interglacial marine episode, i.e., oxygen isotopic stage 5) deposits and for the term Monastirian which was incorporated to the standard Mediterranean terminology for Quaternary marine shorelines early in the twentieth century. For a long time Monastir was the type locality for the 18–20 m terrace. This classic, widely quoted term was finally and definitely dropped when it was established that crustal deformation had occurred near Monastir (Paskoff and Sanlaville 1981). The area is characterized by a triangular wave-cut platform (Fig. 4) which dates back to the late Quaternary (oxygen isotopic substage 5e) and has been affected by two main faults. The Wadi Tefla fault which trends north-east is a normal fault which dislocates the platform in two levels and has a maximum vertical throw of 15 m. It was erroneously considered to be a former sea cliff separating two

Faulted Coasts,

(1) low rocky coastline, (2) sea cliff, (3) erosional scarp of tectonic origin, (4) normal fault, (5) strike-slip fault, (6) tilting, (7) wave-cut platform dating back to the last interglacial age (oxygen isotopic substage 5e), (8) former coastal barrier dating back to the last interglacial age (oxygen isotopic substage 5e), (9) contour line in meters

distinct marine terraces. The NNW–SSE Skanes–Khniiss fault is a major fault of regional significance which displays a vertical displacement that reaches 50 m. It also shows a sinistral strike-slip component characterized by an horizontal movement of at least 500 m. The fault has been active in historical times since it cuts a Roman mosaic on a floor of a house which was built in the second century AD

Fiord or Estuary Coasts and Fault Control

In plan view, coasts developed on intrusive and metamorphic terrains may show intersecting linear patterns of fiords or estuaries, depending on the latitude, marking former glacial or fluvial erosion exploiting the structural weakness of faults. For instance, in southernmost Chile, especially between 44°S and 55°S lat., fiords regionally named *canales*, penetrate inland. They correspond to glacial troughs which were eroded and overdeepened during the last Pleistocene glaciation by active Andean glaciers, mainly in Jurassic granitic rocks. The fiord pattern is strikingly controlled by fault lines which are mainly oriented N–S, NE–SW, and NW–SE. Fault lines were selectively exploited by eroding glaciers. Fiords form a dense network of long marine arms, characterized by straight stretches and right angles (Paskoff 1996).

As already stated by Mclean (1982), the concept of faulted coast has now to be used in a broader sense than initially defined by the pioneers of coastal geomorphology. It encompasses not only cliffs controlled in some way or other by faulting, but also landforms found in the coastal belt which are directly or indirectly related to lines along which vertical or horizontal movements of tectonic origin have taken place.

Definitions

In coastal research, the terms “geochronology” or “geochronostratigraphy” are used to determine time scales for coastal processes and coastal evolution utilizing relative stratigraphic techniques (morpho-, pedo-, bio-, lithostratigraphy) and absolute dating methods, whereas relative and absolute approaches complement each other.

Dating Methods

In the last 30 years, applications of the numerical (“absolute”) dating of coastal structures, sediments, and processes were improved, new dating methods were established, and the precision and accuracy of existing age determination methods were considerably increased. Numerous papers and some books describe dating techniques in Quaternary sciences in detail (e.g., Rink and Thompson 2015; Malainey 2011; Walker 2005).

Mass spectrometric radiocarbon, thorium-230/uranium-234 isotope (Th/U), electron spin resonance (ESR), optically stimulated luminescence (OSL), and terrestrial cosmogenic nuclide (TCN) dating are the most commonly used absolute dating techniques in coastal research (Table 1). In addition, paleomagnetic dating has proved useful for a differentiation of marine and littoral sequences of the Middle and Early Quaternary (e.g., Garces 2015; Jovane et al. 2013), and the

amino acid racemization (AAR) method is a relative chronostratigraphic method that needs calibration with other numerical approaches like radiocarbon or Th/U dating (e.g., Demarchi and Collins 2015; Wehmiller 2013).

Radiocarbon (¹⁴C) Dating

The importance of the radiocarbon method for dating Holocene and Late Pleistocene marine terraces, beaches, and other coastal features cannot be overestimated. It is the most common and widely applied dating method in geochronology.

Carbon-14 (¹⁴C) is a radioactive carbon isotope with a half-life of 5730 ± 40 years. However, ¹⁴C ages are calculated using the original Libby half-life of 5568 ± 30 years. The ¹⁴C isotope is produced in the upper atmosphere by interactions between nitrogen atoms (¹⁴N) and cosmic rays. As part of CO₂ molecules, ¹⁴C mixes with atmospheric carbon in the form of the stable isotopes ¹²C and ¹³C. The natural concentration of radioactive ¹⁴C in the atmosphere is approximately 1.176×10^{-12} atoms per ¹²C atom, and the ¹⁴C content in living organisms is in equilibrium with the atmospheric ratio or their specific environment (e.g., freshwater, saltwater). The CO₂ exchange between the organism and its environment discontinues with death, and ¹⁴C decays to ¹⁴N. Radiocarbon ages are expressed in years ¹⁴C before present (BP), with BP referring to the time before AD 1950, since human-induced nuclear detonations in the 1950s and 1960s significantly changed the atmospheric ¹⁴C composition.

There are two laboratory methods of radiocarbon dating: the conventional decay counting method, which measures beta rays from the ¹⁴C decay process, and the accelerator mass spectrometry (AMS) technique, which determines the amount of ¹⁴C particles in a sample directly. The AMS technique is more sensitive than the decay counting method, and because of this, counting times (minutes to hours, instead of days to months) and sample weights (less than 1 mg C) are greatly

Geochronology, Table 1 Some important dating methods in coastal research (⁺frequently used, but little suited for this dating method)

Method			Dating material	Time scales to be dated	Major problems influencing dating results
<i>Absolute dating methods</i>	<i>Isotope dating methods</i>	<i>Radiocarbon (¹⁴C)</i>	All carbon-containing material, e.g., wood, charcoal, peat, mollusk shells*, coral*, foraminifera*, ostracods*	Holocene up to Late Pleistocene conventional ¹⁴ C method: 20 to 30 ka ¹⁴ C BP; AMS ¹⁴ C method: approx. up to 50 ka ¹⁴ C BP	Variability in atmospheric ¹⁴ C (cosmic, Suess and nuclear bomb effects); contamination of samples by younger C-bearing material; * marine reservoir effect
		<i>Thorium-230/Uranium-234 (²³⁰Th/²³⁴U)</i>	Coral, mollusk shells ⁺ , bones ⁺ , teeth ⁺ , speleothems ⁺ , travertines ⁺	Holocene up to Late Middle Pleistocene coral: approx. up to 200 ka BP. Mollusk shells: approx. up to 130 ka BP (less reliable)	⁺ Isotope mobilization, esp. uranium migration (radiometric system may not be closed); variability of ²³⁴ U/ ²³⁸ U ratio in seawater
		<i>Terrestrial cosmogenic nuclides (TCN)</i>	Quartz (¹⁰ Be, ²⁶ Al) and carbonate (³⁶ Cl)-bearing sediments and surfaces	Holocene to Pliocene	Inheritance of nuclides from pre exposition, eroding surfaces, large background levels in rocks
	<i>Radiation induced dosimetric dating methods</i>	Optically stimulated luminescence (OSL)	Dune sands, littoral sands (and cobbles), storm and tsunami deposits	Holocene up to Late to Middle Pleistocene at least up to 300 ka BP	Incomplete bleaching; isotope mobilization, esp. uranium migration; variations in water contents
		Electron spin resonance (ESR)	Coral, mollusk shells, foraminifera, some gastropods	Holocene up to middle Pleistocene coral: up to 400–600 ka BP. Mollusk shells, foraminifera, and gastropods: up to 200–300 ka BP (upper dating limit still unknown)	Isotope mobilization, esp. uranium migration; recrystallization of sample
<i>Relative dating methods</i>		<i>Paleomagnetic dating</i>	All material with stable magnetic remanence, e.g., fine-grained coastal sediments	Middle and Early Quaternary, limited to paleomagnetic reversals and events	Destruction of primary magnetic signal and acquisition of secondary magnetization
		<i>Amino acid racemization (AAR)</i>	Mollusk shells	From several 100 a to several 100 ka BP	Results require calibration through absolute dating techniques; racemization rates may vary between genera; diagenesis temperature histories may differ between geographic regions

reduced. Dating is theoretically limited to ca. 50,000 years, however, due to sample or laboratory contamination rather to 30,000 years.

Since the 1960s, the radiocarbon method has been used successfully for dating Holocene and Late Pleistocene samples. The ¹⁴C method delivers reliable results for wood, charcoal, and plant matter (e.g., peat, seeds, leaves), while the dating of humus, speleothems, calcretes, bones, and teeth is frequently inaccurate. In coastal research, the ¹⁴C dating method is widely applied to the dating of marine macrofauna (e.g., mollusk shells, coral) and microfauna (e.g., foraminifera, ostracoda). Radiocarbon dating is also used to date the formation of coastal marshes and peat layers that are used, e.g., as archives for sea-level evolution (Kemp et al. 2017; Gehrels 1999), and it is an excellent tool for geoarchaeological research in coastal settings where it can be cross-checked with relative chronologies based on artifacts (Brückner 1997, 2003).

Variations in the production of atmospheric ¹⁴C may be caused by sunspot activity, changes in the intensity of the Earth's magnetic field, or variability in cosmic radiation. These sources of error can be reduced by calibrating ¹⁴C dating results (at present the calibration table covers the last 50,000 years) with a dendrochronologic tree ring calendar (dendrochronology: an absolute dating method based on the counting of tree rings); with Th/U-dated corals, speleothems, and foraminifera; and with varved sediments (Reimer et al. 2013). In addition, marine samples may be influenced by the so-called marine reservoir effect, which is caused by the variability in the ¹⁴C concentration in seawater. Deep ocean water has lower ¹⁴C contents than the atmosphere. The ¹⁴C dating of marine fauna (mollusks, coral, microfauna) from shorelines influenced by upwelling deep ocean water results in ¹⁴C ages that are too old. The global mean reservoir effect for marine carbonates is approximately 400 years but varies spatially and temporally.

Case Study: ^{14}C Dating of Beach Ridges in Spitsbergen

The littoral zone of northern Andréelund (northern Spitsbergen) is characterized by more than 100 beach ridges ranging in elevation from present sea level to 70 m above. They represent uplifted former shorelines (Brückner and Schellmann 2003; Brückner et al. 2002; Forman et al. 2004). Two conditions led to their formation: (a) The West Spitsbergen Current, the northernmost continuation of the Gulf Stream extending up to 80°N , created seasonally ice-free conditions in fjords. This allowed wave action, which caused the formation of beach ridges. (b) The current elevation of these beach ridges is a result of coastal uplift due to the glacio-isostatic rebound following the last deglaciation.

The radiocarbon dating results of mollusk shells (Fig. 1) illustrate (a) the onset of deglaciation and the beginning of beach ridge formation in the Allerød Interstadial ($11,970 \pm 60$ years ^{14}C BP, minus the reservoir effect of approximately 400 years) due to the arrival of the West Spitsbergen Current; (b) that fjords were blocked by sea ice during the Younger Dryas cold phase (this period of no beach ridge formation ranged approximately from 11,100 to 10,600 ^{14}C BP (minus the reservoir effect; see above)); and (c) that the major glacio-isostatic uplift occurred between 12,000 and 9200 years ^{14}C BP (minus the reservoir effect; see above) and amounted to more than 140 m. At approximately 12,000 ^{14}C BP, eustatic sea level was at least 70 m lower than today. Since then, the oldest beach ridges have been uplifted from less than 70 m below up to 70 m above present sea level.

Thorium-230/Uranium-234 Isotope ($^{230}\text{Th}/^{234}\text{U}$) Dating

The thorium-230/uranium-234 ($^{230}\text{Th}/^{234}\text{U}$) dating method is the most frequently used uranium isotope age determination technique. In coastal research, this method is utilized for dating marine and lacustrine carbonates (Edwards et al. 2003). It is used, first of all, for dating Middle and Late Quaternary corals (Zhao and Collins 2011), sometimes for dating submerged coastal speleothems (Stirling 2015), and to a lesser extent for dating mollusk shells.

The method is based on the fact that coral and mollusk shells during formation take up the mother nuclide ^{234}U from seawater without its daughter nuclide ^{230}Th . Modern corals contain uranium with an initial $^{234}\text{U}/^{238}\text{U}$ ratio of 1.15 ± 0.03 (Edwards et al. 2003), and after the organism's death, ^{234}U decays to ^{230}Th . The ^{230}Th half-life of 75.4 ka determines the upper dating limit of this method, which is reached at 500 to 600 ka (approximately seven times the half-life of ^{230}Th). However, reliable data have been provided mainly for the past 130 to 200 ka.

The uranium-234 and thorium-230 isotope content can be determined by α -counting (alpha-spectrometry), by thermal ionization mass spectrometry (TIMS), as well as by inductively coupled plasma mass spectrometry (ICP-MS) or by laser-ablation multi-collector ICP-MS (Spooner et al. 2016). The mass spectrometric methods offer a higher precision (the analytical error is between 0.5 and 7%), require smaller sample sizes (0.2 to 0.05 g), and need shorter measurement times (MC-ICP-MS only some minutes).

Geochronology, Fig. 1

Deglaciation and evolution of beach ridges in Northern Spitsbergen (Woodfjord, Wijdefjord) based on ^{14}C dating. Beach ridges (in m above sea level) are represented by circles. All ages are uncalibrated ^{14}C years BP. The average reservoir effect for marine carbonates (approximately 400 years) needs to be considered for the correlation of the ^{14}C ages to geologic time periods (e.g., Younger Dryas). Articulated shells give reliable ^{14}C ages for beach ridge formation. The ^{14}C ages of coastal features based on single shells and shell debris are frequently overestimated since this material may have been relocated (modified after Brückner and Schellmann 2003)

Although the precision of Th/U dating has significantly improved due to advances in analytical techniques, numerous sources of error still limit the accuracy of the approach. One key assumption in Th/U dating is that neither the mother nor the daughter nuclides are relocated after uranium accumulation in the coral structure or mollusk shell (a closed system). However, uranium is easily soluble in an oxidation environment and may be added or removed. The resulting error in age determination can amount to tens of thousands of years and more. Partially recrystallized coral samples are neither suited for Th/U dating, since uranium and thorium may be mobilized in the process of calcite formation through the recrystallization of the aragonitic coral structure. Th/U and ESR dating results of paired coral samples from the MIS 5a-1 coral reef near the south point of Barbados (Fig. 2) illustrate very well that the apparently minor analytical errors (precision) of TIMS Th/U ages (less than 1%, ESR between 5% and 8%)

do not necessarily guarantee a better temporal resolution (Schellmann et al. 2004).

Mollusk shells are more prone to uranium and thorium migration than coral. Therefore, they are less suited for Th/U dating (Kaufman et al. 1971). While corals absorb approximately 3 ppm uranium from seawater, mollusk shells take up most of their uranium (approximately 0.2–11 ppm) after death from ground and seepage water. The majority of this uranium is taken up within the first few centuries and millennia after their death (Schellmann et al. 2008). However, later isotope exchange with the surrounding environment is possible. The variability of the $^{234}\text{U}/^{238}\text{U}$ ratio in seawater can also cause errors in the Th/U dating of Pleistocene coral and mollusk shells (Bard et al. 1992).

Despite all potential sources of error, mass spectrometric Th/U dating of corals was utilized for the extension of the ^{14}C calibration curve to up to 50 ka BP (Reimer et al.

Geochronology, Fig. 2 Evolution of the beach ridge plain on Phra Thong Island (KPT), SW Thailand, on the basis of quartz OSL data. While the eastern part of the island formed during MIS 5e, the western ridge plain section was accumulated – with varying progradation velocities – during the last ~6000 years. Quartz OSL ages of tsunami-laid

sands archived in peat of the swales indicate predecessors of the 2004 Indian Ocean Tsunami that inundated the island 500–600 years ago (PT1), 900–1100 years ago (PT2), and ~1800 years ago (PT3). Details in Brill et al. (2015, 2012)

2013). The current knowledge of Last Interglacial sea-level changes (75 ka to 130 ka BP) is largely based on α - and mass spectrometric Th/U dating of fossil coral. Even the Th/U dating results of Penultimate Interglacial coral reefs (around 200 ka BP) can reach considerable accuracy, while the Th/U dating of Middle Pleistocene and older coral samples is not reliable due to their increased weathering and the still unknown $^{234}\text{U}/^{238}\text{U}$ ratio in seawater during those times. To summarize, Th/U dating of fossil coral produces accurate results for up to the last 200 ka BP, while the Th/U dating of mollusk shells is less reliable.

Optically Stimulated Luminescence (OSL) Dating

Luminescence dating techniques are typically used to determine the time period that has elapsed since sediment grains have last been exposed to daylight during transportation. The fundamental concept of this method (Preusser et al. 2008; Aitken 1998) is the use of naturally occurring semiconducting crystalline minerals, such as quartz and feldspar, as natural dosimeters. These minerals record the time span they have been exposed to ionizing radiation generated by the decay of uranium, thorium, potassium, and rubidium in the surrounding sediment, as well as by the influence of cosmic rays while their sediments were morphodynamically stable. Ionizing radiation transfers charge within the crystal lattice by moving electrons from their stable state to so-called electron traps. In the traps, electrons are stable until released by exposure to heat or sunlight, whereas the number of trapped electrons increases with the time and dose of natural radiation. The released electrons recombine with so-called luminescence centers, a process accompanied by the emission of photons. This light emission is the luminescence signal that is used for dating. For coastal sediments, such as foredunes or littoral sands, the resetting event (called “bleaching”) is the exposure of the sand grains to daylight during transport by wind or waves.

To determine the luminescence signal accumulated in a mineral, different modes of laboratory stimulation can be used. While luminescence emissions evoked by light (optically stimulated luminescence, OSL) are sensitive enough to sunlight resetting in nature for being applicable to a large variety of coastal sediments, luminescence signals stimulated by heat (thermoluminescence, TL) are less light sensitive and, therefore, lately not used anymore for dating coastal sediments. The most commonly applied OSL techniques are infrared stimulated luminescence (IRSL) for feldspar and blue light stimulated luminescence (BSL) for quartz.

Luminescence techniques measure the radiation dose (equivalent dose, D_E) that has accumulated in the minerals

since the last resetting of charge, either using the additive dose method or the regeneration method. These can be conducted on many aliquots of a sample (multiple aliquot approach), on one aliquot of a sample (single aliquot approach), or on one grain of a sample (single grain approach). However, since the late 1990s, in the large majority of all studies, the single aliquot regenerative dose (SAR) approach of Murray and Wintle (2000) is applied. While quartz is usually the preferred dosimeter for Holocene deposits, feldspar may be advantageous for older sediments due to a more extended dating range. However, feldspars are often affected by signal loss over time that is not related to heat or light exposure (anomalous fading). Alternative approaches for dating Middle to Late Pleistocene deposits have come up during the last 10 years in the form of post-infrared infrared (pIRIR) stimulated luminescence dating (Thomsen et al. 2008) or thermally transferred OSL (TT OSL; Wang et al. 2006).

In addition to dose determination, measurements of the environmental ionizing radiation rate (dose rate or annual dose, D') are required for the age calculation of a sample. D' is estimated in the laboratory using, e.g., gamma spectrometry or directly in the field using a portable gamma spectrometer. The sample age is then calculated by dividing D_E (in Gy) by the annual dose D' (in Gy/ka). Luminescence methods have been successfully used for generating deposition chronologies ranging from a few years to at least 100–150 ka using quartz and up to at least 300 ka using feldspar. The precision reached in luminescence dating is typically 5–15%.

Luminescence methods are applied to a wide range of depositional environments. While aeolian sediments, including coastal dune sands, are best suited for luminescence dating due to prolonged exposure to light during wind transport, water-laid coastal sediments may be suited as well (Lamothe 2016; Jacobs 2008) depending on water depth and the concentration of suspended sediment. Complete bleaching of coastal sediments prior to their deposition is particularly likely in shallow marine environments that are located in regions with intense insolation. Sand- to silt-sized sediments have been dated from a large range of coastal settings, including littoral deposits (Brill et al. 2015; Reimann et al. 2010), intertidal deposits (Zander et al. 2007; Madsen et al. 2005), tsunami deposits (Brill et al. 2012; Huntley and Clague 1996), and storm deposits (Brill et al. 2017; May et al. 2015). Lately, also cobble-sized beach sediments have been dated using OSL (Simms et al. 2011). While signal resetting is, thus, usually sufficient to allow OSL dating of coastal sediments, significant inaccuracies may be introduced when radioactive disequilibria (e.g., due to uranium uptake or excess in coastal carbonates) complicate dose rate determination (Zander et al. 2007).

Case Study: OSL Dating of Beach Ridge Formation and Tsunami Inundation in Thailand

The beach ridge plain on Phra Thong Island, SW Thailand, provides a good example for the applicability of OSL dating in coastal settings (Fig. 2). Quartz OSL ages of the beach ridges reveal that island formation started already during the Last Interglacial sea-level highstand (MIS 5e) and continued – with varying velocities – during the last 6000 years following the mid-Holocene sea-level maximum (Brill et al. 2015). At the same time, quartz OSL dating of tsunami-laid sand sheets archived in the peat of the swales indicates ages of 490–550, 925–1035, and 1740–2000 years for the last three predecessors of the 2004 Indian Ocean tsunami (Brill et al. 2012).

Electron Spin Resonance (ESR) Dating

The first systematic studies and applications of electron spin resonance (ESR) dating of corals and mollusk shells were conducted in the 1980s. Since then, a large number of Pleistocene coastal features and sediments have been dated using ESR. Like luminescence dating, ESR dating is a radiation-induced dosimetric dating approach. It is based on the radiation damage in minerals that increases with age and is caused by ionizing radiation from natural radioactivity and cosmic rays. These damages generate paramagnetic centers and radicals that can be measured using ESR (Schellmann and Radtke 2015).

An ESR age derives from the ratio of the accumulated radiation dose D_E to the dose rate D' as already described for OSL. However, unlike OSL, the D_E in ESR dating usually is still determined by an additive dose method, for which 20 or more aliquots of the same sample are stepwise irradiated with increasing γ -doses. Trapped electrons increase in number with increasing gamma doses and, thus, cause the amplitude of the ESR dating signal to increase. The D_E is determined by extrapolating the resulting dose response curve to zero ESR intensity. D' can be determined by the same approaches as used for estimating the dosimetry of OSL samples (in the laboratory or in the field). The correct determination of D' and D_E is essential for any ESR age estimate.

Schellmann et al. (2008) and Blackwell et al. (2016) describe ESR dating of Quaternary materials and discuss their accuracy and precision. In the last years, both precision and accuracy of ESR dating of fossil corals and mollusk shells have improved due to the higher resolution of ESR measurements and due to new techniques for D_E determination (Schellmann and Radtke 1999, 2001). However, ESR ages can deviate by several thousand years, if the natural radiation dose of the sample was affected by uranium or thorium mobilization or by changing moisture conditions in the past. Further problems may arise from the heterogeneity of the

surrounding sediments and from the open system behavior of shells with respect to uranium migration.

ESR dating results of mollusk shells that were embedded in heterogeneous beach sediments are most affected by these sources of error. Dating uncertainties can reach more than 15%. Therefore, ESR dating results for mollusk shells from littoral deposits are frequently limited to the mere differentiation between Holocene, Last Interglacial, Penultimate Interglacial, and older sediments (Schellmann and Radtke 2000).

On the other hand, dating of coral originating from relatively homogeneous reef limestone can generally be accomplished with errors of 5 to 8%. Substages of sea-level highstands (e.g., Last Interglacial Oxygen Isotope Substages 5a, 5c, and 5e) can be discriminated due to improvements in the determination of the D_E . ESR ages of corals from the Late Pleistocene are now as accurate as those based on Th/U dating (Fig. 3). Therefore, the application of both methods simultaneously is recommended for the dating of coral up to 200 ka BP.

The ESR method allows for the dating of corals and mollusk shells for a larger time span than any other Quaternary dating method. The lower dating limit lies at a few thousand years BP, and the ESR method should theoretically allow for the dating of corals and mollusk shells that are a few million years old. However, numerous ESR dating results for mollusk shells and coral illustrate that the upper dating limit lies at 200 to 300 ka and 400 to 600 ka, respectively. This limit is largely dependent on changing conditions due to diagenesis and weathering. For example, the recrystallization of the aragonite coral structure or mollusk shell can cause considerable underestimates of ages, since it eliminates previously stored radiation.

ESR has been widely applied to sequences of raised coral reef terraces with ages of up to 500–600 ka, e.g., terraces on Sumba island (Pirazzoli et al. 1991) and on Barbados (Radtke and Schellmann 2006; Schellmann and Radtke 2004a). Mollusk shells and gastropods with ages ranging up to 200 to 300 ka were also dated using ESR, e.g., mollusk shells at the Patagonian Atlantic coast (Schellmann and Radtke 2000) or Late Pleistocene gastropods in eolianites on Cyprus (Schellmann and Kelletat 2001).

Case Study: ESR Dating of Pleistocene Coral Reef Terraces in Southern Barbados

ESR dating of the fossil coral reef terraces on Barbados delivers an impressive example for the application of this method (Fig. 4). In southern Barbados, Late and Middle Pleistocene coral reef terraces rise up to 63 m above present sea level. The ESR and similarly the TIMS $^{230}\text{Th}/^{234}\text{U}$ ages increase with height up to 224 ka (MIS 7). The age-height relationships allow for the calculation of neotectonic uplift rates in Barbados and of paleosea-level changes (Schellmann and Radtke 2004a; Schellmann et al. 2004; Potter et al. 2004).

Geochronology, Fig. 3 ESR and TIMS Th/U ages ($\delta^{234}\text{U} > 141$ and $< 157\text{‰}$) of MIS 5a-1 coral reef terrace near Inch Marlowe Point, southern coast of Barbados (modified after Schellmann and Radtke 2004a and Schellmann et al. 2004)

Terrestrial Cosmogenic Nuclide (TCN) Dating

Dating techniques based on the measurement of terrestrial cosmogenic nuclides (TCN) determine either exposure ages or burial ages for rock surfaces and sediments over time scales of thousands to millions of years (Dunai 2010; Gosse and Phillips 2001). TCN are produced in the uppermost rock formations where these are exposed to cosmogenic radiation. At the Earth's surface, cosmic radiation is dominated by the secondary cosmic ray flux that results from interactions of primary cosmic radiation (i.e., mostly protons) with the atmosphere. These secondary particles, mainly high-energy nucleons and muons, interact with the mineral atoms through different mechanisms (i.e., spallation, thermal neutron capture, and muon capture) to generate new *in situ* nuclides in the exposed rocks or sediments. The TCN production rates vary with geographical site characteristics such as latitude, altitude, and local shielding (e.g., surrounding topography) and decrease exponentially with depth below surface. While nucleons dominate production rates in the uppermost 2–3 m, their contribution becomes insignificant below this depth where production is essentially controlled by muons.

TCN that (i) are stable or long-lived radioactive (i.e., half-life > dating range), (ii) have low background levels in the

rocks that shall be dated, (iii) are not significantly affected by meteoric input, (iv) can be produced in common rock types, and (v) are well understood in terms of their production pathways have been increasingly used for dating applications in Earth sciences since the development of AMS facilities in the late 1980s which allows their precise measurement (Dunai 2010). Until now, mainly the stable noble gases ^3He and ^{21}Ne , as well as the radionuclides ^{10}Be , ^{26}Al , and ^{36}Cl , are routinely applied. While the stable TCN can provide exposure ages for pre-Quaternary surfaces, ^{36}Cl , ^{26}Al , and ^{10}Be , with half-lives of ~ 0.3 Ma, ~ 0.7 Ma, and ~ 1.4 Ma, respectively, allow to establish exposure and burial histories that theoretically cover the entire Quaternary. However, inheritance (i.e., nuclide accumulation prior the dated event), large background levels, and erosion of unstable surfaces may constitute significant challenges for accurate dating.

In coastal contexts, TCN applications have focused on dating the exposure time of quartz cobbles in depositional marine terraces (e.g., Binnie et al. 2016; Perg et al. 2001), or the exposure time of abrasive platforms (Regard et al. 2012), using either ^{10}Be or a combination of ^{10}Be and ^{26}Al . Lately, Ramalho et al. (2015) and Rixhon et al. (2017) used ^3He and ^{36}Cl to determine exposure ages for wave-emplaced basaltic and coral boulders, respectively.

Geochronology, Fig. 4 ESR and TIMS Th/U ages of uplifted Middle and Late Pleistocene coral reef terraces in a transect on southern Barbados (slightly modified after Schellmann and Radtke, 2015). Details in Schellmann and Radtke (2004a, b)

Amino Acid Racemization (AAR) Dating

The amino acid racemization (AAR) dating technique is a relative age determination method for various organisms like marine mollusks, coral, or foraminifera (e.g., Demarchi and Collins 2015; Wehmiller 2013). AAR is applied to time scales ranging from hundreds to hundreds of thousands of years. The method is based on the rate of racemization and epimerization of indigenous amino acids preserved in mollusk shells or corals from coastal deposits. This protein degradation processes are crucially influenced by the temperature history during diagenesis and the rate of hydrolysis of residual proteins.

Several uncertainties in the applicability and reliability of AAR remain, since (a) racemization rates may vary between genera and (b) diagenesis temperature histories may vary between different geographic settings. The AAR method seems to be reliable for local and regional aminostratigraphic units only. Since AAR is a relative dating technique, its results need to be calibrated using numeric dating methods like radiocarbon or U-series dating.

Paleomagnetic Dating

Paleomagnetic dating determines the natural remanent magnetization of sediments and correlates it to the known paleomagnetic polarity stratigraphy. Permanent magnetism is carried by ferromagnetic minerals that are minor constituents of almost all rocks. Magnetic minerals align to the Earth's magnetic field and keep that orientation when they are deposited or precipitated in the sedimentary matrix during early diagenesis. Garces (2015), Calvo-Rathert (2015), and Hambach et al. (2008) describe the physical properties and some applications of this method.

In the Quaternary several instabilities of the Earth's magnetic field occurred in terms of variations in field intensities and field directions, forming geomagnetic reversals and excursions (Singer 2014; Hambach et al. 2008). They can be used for relative dating of sedimentary and volcanic rocks. The paleomagnetic field reversals at the base of the so-called normal Brunhes and reverse Matuyama chrons at 0.78 Ma and 2.6 Ma, respectively, are the most important polarity changes of the Earth's magnetic field in recent geological history. The Jaramillo normal (c. 0.9 to 1.1 Ma) and Olduvai normal (c. 1.7

to 1.9 Ma) subchrons are two important reversals within the Matuyama chron. At least 27 short-lived field excursions occur within the Brunhes (14) and Matuyama (13) chrons, even though their global evidence is still under research. The most prominent short-lived excursion is the “Blake Event” (approximately 120 ka), which seems to be a worldwide reversed interval (Singer 2014).

Sample applications of the paleomagnetic method include the dating of marine terraces in southern Italy (Brückner 1980) and the dating of a sequence of beach ridges and coastal dunes at the Moroccan Atlantic coast (Brückner and Hambach, unpublished data). The paleomagnetic method requires a continuous sequence of coastal formations and a narrow sampling strategy. Paleomagnetic dating allows to differentiate within the Middle and Older Quaternary, where other dating methods fail. However, lately paleomagnetic dating has also been applied to tentatively determine the relocation of wave-emplaced coastal boulders during the Holocene (Sato et al. 2014).

Summary

In the context of dating Quaternary coastal structures, sediments, and processes, new dating methods were established, and the precision of traditional methods was considerably increased. Besides age determinations by relative methods like the amino acid racemization (AAR) and the paleomagnetic method, the use of numerical dating techniques has significantly increased. Fossils like corals, mollusk shells, or foraminifera can be dated by radiocarbon (^{14}C), thorium-230/uranium-234 ($^{230}\text{Th}/^{234}\text{U}$), or electron spin resonance (ESR) and aeolian or beach sediments by optically stimulated luminescence (OSL). Each dating technique has its own time range, precision, and accuracy, which has to be taken into account.

Geodesy

Mike P. Stewart
School of Spatial Sciences,
Curtin University of Technology, Perth, Australia

According to the traditional classical definition, attributed to F. R. Helmert in 1880, geodesy is *the science of the measurement and mapping of the earth's surface*. Nowadays, this definition is deemed to encompass determination of the topography of the earth's landmasses, the bathymetry of the seafloor, the shape of the surface of the ocean, and form and nature of the earth's internal and external gravity field.

History

The origins of modern geodesy can be traced to antiquity. The ancient Greeks speculated on the shape of the earth with Pythagoras, and later Aristotle, introducing the concept of a spherical earth. The first scholar to make a scientific estimate of the shape of the earth was Eratosthenes of Alexandria (276–195 BC) who obtained a value for the circumference of earth to within 2% of modern estimates. A later estimate by Posidonius (135–51 BC) was used by Ptolemy (AD 90–168) to produce the monumental eight volume *Guide to Geography*, which contained maps of the world destined to be the definitive work for the next fifteenth centuries. Columbus, based on such maps, was to underestimate the distances from Europe to India and Asia and, in turn, discover the Americas. Advances in astronomy, instrumentation and physics in the sixteenth and seventeenth centuries led to Isaac Newton (1643–1727) and Christian Huygens (1629–95) proposing that the earth was not spherical, but flattened at the poles. This proposal led to some controversy and, it was not until the late eighteenth century, following increasingly accurate measurements on the earth's surface, that an ellipsoidal model for the shape of the earth was universally adopted.

Essential Geodetic Concepts

Definition of the size and shape of the earth does not usually involve surface topography or the bathymetry of the oceans, but the surface of mean sea level and its theoretical continuation under the continents. Topographic heights and bathymetry are measured relative to this hypothetical surface which is known as the geoid. By definition, the geoid represents an equipotential surface and is therefore a direct representation of the earth's gravity field. The geoid is a mathematically complex surface, its shape being strongly influenced by irregular mass distributions below the earth's surface. It is thus unsuitable as a reference surface for a geometric figure of the earth. For further details on the earth's gravity field and the geoid, the reader is referred to Heiskanen and Moritz (1967).

For geodetic calculations, such as computing geodetic latitude and longitude and defining map projections (e.g., Bugayevskiy and Snyder 1995), an ellipsoid of revolution (a three-dimensional surface generated by rotating an ellipse 360° about its minor axis) is defined. This simple figure is known as a reference ellipsoid and is defined by a semimajor axis (equatorial radius) and semiminor axis (polar radius). The earth's semimajor axis is about 21 km greater than the semiminor axis, with the flattening being approximately 1/300. A commonly used reference ellipsoid is that associated with the World Geodetic System 1984 (WGS84) (NIMA 1997).

For geodetic measurements, the concept of geodetic datum is introduced. A geodetic datum is a three-dimensional representation of the surface of the earth through a framework of discrete points whose coordinates and elevation (either above mean sea level or a reference ellipsoid) are accurately known. In individual regions, datum coordinates and computations are based on a local reference ellipsoid, which corresponds closely to the shape of the geoid in that area. Modern satellite techniques, such as the Global Positioning System (GPS) (*q.v.*), rely on geocentric reference ellipsoids which have the center of the earth as the origin. To ensure compatibility between GPS coordinates and coordinates in the framework of the local geodetic datum, a mathematical function defining the transformation of the coordinates between the two systems must often be computed. A geodetic datum forms the basic structure for densification surveys which, in turn, can be incorporated into maps or Geographic Information System (GIS) (*q.v.*) databases. The concepts of geodetic datums and reference systems are covered in detail by Torge (1991).

Applications of Geodesy

Space geodetic measurement techniques (descriptions of very long baseline interferometry (VLBI), satellite laser

ranging (SLR), and GPS are given in Seeber (1993)) are used to define international geodetic datums, such as the International Terrestrial Reference Frame (ITRF), which provide the basic infrastructure for positioning and navigation on the surface of the earth. These reference frames are used for global and regional plate tectonic studies, measurement of isostatic rebound, and connection of *tide gauges* (*q.v.*) for monitoring the levels of the world's oceans (see also “► [Tidal Datums](#)” (*q.v.*)). They are also critical for satellite orbit tracking required for such applications as satellite *altimetry* (*q.v.*) and *SAR* (*q.v.*) studies. Global geodetic measurements are also used to derive parameters that can describe variations in the rotation of the earth (e.g., length of day, polar precession, and nutation), and the dynamics of the atmosphere, oceans, and solid earth (Lambeck 1988).

Local geodetic measurements rely on survey instrumentation such as electronic distance meters (EDM), precise levels and *GPS* (*q.v.*) receivers. Such measurements are primarily used for mapping purposes, providing local control for *photogrammetry* (*q.v.*) and *remote sensing* (*q.v.*), and for engineering applications such as monitoring physical changes in man-made structures and ground surfaces. For a complete appraisal of geodesy and terrestrial surveying, the classic text is Bomford (1980).

Geographic Information Systems (GIS)

Shawn M. Boeser¹ and Sarah M. Hamylton²

¹Vashon, WA, USA

²Wollongong University, Wollongong, NSW, Australia

Definition

Geographic Information Systems (GIS) are computerized spatial decision-making tools that work with place-based information and allow users to display, manage, and analyze geographic data. Since coastal features typically show distinct spatial patterning, coastal managers and scientists have incorporated this technology from its beginnings. However, coastal data often represent dynamic, multidimensional systems that present problems to this historically land-based technology.

History

The concept of a GIS originated from noncomputerized decision-making techniques. One classic example is a decision-making technique developed by Ian McHarg, a landscape architect and author of *Design with Nature*. McHarg's method for identifying suitable locations for development was based on defining the most favorable characteristics of various sets of information such as slope, soil type, geology, land use, and accessibility and then combining the layers into a composite map (McHarg 1969). Although McHarg's technique may be carried out in an analog fashion, it is a popular example of the power of applying digital computer technology.

The beginning of the modern, digital, GIS began in the late 1960s. Several efforts in developing digital spatial systems began concurrently and involved applications for urban planning, transportation, natural resources, and the US Census. The first use of the term GIS was the Canada Geographic Information System, implemented in 1964 to identify marginal agricultural lands for rehabilitation (Foresman 1998; Wright and Bartlett 2000).

Data Models

A data model represents the spatial entity and its relationship to the real world. There are two primary data models: raster models and vector models. Raster models generally depict continuous data by representing data points in a regular pattern of cells. The size of the cells, for example, 10 m by 10 m, defines the geometric resolution and a series of row and column coordinates define the spatial extent. Continuous data commonly depicted with a raster model include surface

elevation, precipitation, and satellite image data such as land cover.

Vector models are topological, representing discrete data with nodes and lines that can be represented as points, lines, or polygons (Bernhardsen 1992). The node may define a starting point, an intersection, an end point, or any point along a line. The topological model retains the relationship and connectivity between and among points, lines, and polygons. For example, a series of nodes and lines may define two adjacent counties; the shared border is captured and stored only once in a vector model and that relationship remains intact even when the geometry is changed.

Functionality

A GIS typically uses hardware and software that allows the following functionality:

- Data input/capture
- Data storage/management
- Data manipulation
- Data analysis
- Data output and display

If data are not already in a digital form, data capture may be a time-consuming component of building a GIS. Coastal scientists use a combination of primary and secondary data. Examples of primary data capture techniques include hand-digitizing maps, electronic scanning that converts points and lines, Global Positioning Systems (GPS) that digitally record surveyed locations, manual entry of geographic coordinates, and the use of instruments with in-built GPS technology that add geographic referencing to information collected, such as bathymetric survey points from sonar, above-water aerial images from drones, and below-water images from autonomous underwater vehicles (AUVs) (see Fig. 1). Attribute characteristics are assigned once geographic entities are digitally captured. For example, a river (the entity) may be hand digitized and its name would be stored separately as an attribute. At minimum every attribute will have a unique identification code and there may be any number of additional

Geographic Information Systems (GIS), Fig. 1 Collecting primary spatial data in the coastal zone: (a) A snorkeler towing a GPS along in a floating waterproof bag while taking ground referencing photographs above a coral reef, (b) scuba divers collecting spectral signatures of the seafloor to support broader scale mapping using remote sensing

techniques, (c) a drone collecting imagery from a GoPro above mangroves in Minnamurra River, New South Wales (Photo credit: Mark Newsham). (d) A coupled GPS monitor and side-scan sonar instrument (Photo credit: Frank Sargeant)

attributes allocated to each entity. Secondary data, both base data and thematic data, may be acquired from an ever-growing multitude of sources. Spatial base data, such as roads, rivers, and administrative boundaries, are often easily downloaded from government sources and other public sharing domains. In using secondary data, one must ensure data quality such as completeness, accuracy, currency, and lineage. Acquiring secondary data may also require a conversion process from one proprietary format to another or conversion from one coordinate system or map projection to another.

Data storage and management is conducted using the database management system (DBMS) component of a GIS. Users create, update, and store the geographic entity files and their associated attributes in a DBMS. Metadata, information about the history and extent of the spatial data, should similarly be stored and managed. Once collected and stored in a GIS database, spatial data may be manipulated (queried, classified, and edited) using tools inherent in GIS software packages.

The ability to analyze spatial data is the component that differentiates GIS from desktop or web-based mapping software. GIS software provides tools to analyze distance, direction, connectivity, and proximity through the use of spatial and attribute queries. Furthermore, data modeling tools allow the depiction of two- and three-dimensional characteristics of the earth's surface, subsurface, and atmosphere. The movement of humans or natural features through linear networks such as roads and streams may be modeled. Map overlay analysis involves combining two or more layers of information through logical operations. McHarg's suitability analysis is a perfect example of the use of map overlay analysis.

Finally, data output and display capabilities allow GIS users to prepare graphic images of their results. The images may be printed as paper maps or stored as image files for electronic display or for use in web-based applications.

Coastal GIS

Since coastal data are spatial, GIS technology was recognized early in the 1970s as a useful tool for coastal science applications and for coastal zone management decision-making. The first GIS coastal applications were developed for tasks such as development or tourism planning along coasts (Bartlett 2000). Early efforts to apply GIS were thwarted by the limited availability of software, hardware, trained personnel and data models. Furthermore, the built-in functionality necessary for coastal applications that require three-dimensional and temporal analysis was not available.

The structure of the data model had also limited coastal GIS applications. While raster-based models allow simple programming and high volume storage, their spatial

resolution is compromised. Conversely, vector systems portray finer resolution but inappropriately portray boundaries that are "fuzzy." Dynamic segmentation (network models), object models, and others "hold considerable potential for advancing the utility of GIS within the coastal and marine environment" (Bartlett 2000).

Many coastal environments are controlled by physical and biological processes which can easily be upset by natural or human-induced disturbances. GIS therefore offers an opportunity to work with spatially referenced data to explore, infer, and predict coastal trends in both space and time. These often occur at broad geographical scales that enable scientists or managers to make meaningful observations and statements about the behavior of landforms and biological communities. Table 1 provides some examples of management issues across different types of coastal environment, with corresponding spatial analyses conducted to address these issues.

Unique Challenges for Spatial Analysis in Coastal Environments

Because of the presence of the sea, coastal environments present some unique challenges to the conduct of spatial analysis. These include the variable range of tidal datums particularly for referencing vertical heights (e.g., tidal mean sea level versus chart datum) and the uncertainty that this variability introduces to the definition of coastal boundaries, the rapid speed of change in shoreline features (Ellis 1978), and the practical limitations imposed on conducting fieldwork underwater (Hamylton 2017).

Tidal datums are base elevations for vertical measurements, such as under and above water elevation that are defined by phases of the tide. They are used for establishing coastal boundaries, limits of the territorial sea, water depths, critical shorelines on charts, and the limits of various coastal management responsibilities (Ellis 1978). Hirst and Todd (2003) categorize the problems associated with defining coastal boundaries into describing, visualizing, and realizing problems. Descriptive confusion arises from vague or ambiguous descriptions in legislation and policy documents, references to a datum. In some cases, coordinates are omitted entirely. To visualize or map a coastal boundary, it is necessary to represent it as a digital feature within a GIS. This raises questions of how a coastline should be defined and how accurately it can be mapped. The *Tidal Interface Working Group* of the *Intergovernmental Committee on Surveying and Mapping* have defined some commonly used tidal interface boundaries, including highest astronomical tide, mean high water springs, mean high water, mean sea level, mean low water springs, mean low water, and lowest astronomical tide (McCutcheon and McCutcheon 2003). The need to arrive

Geographic Information Systems (GIS), Table 1 Some examples of spatial analysis supported by GIS across different coastal environments

Coastal environment	Spatial analysis examples
Sandy coastlines	Simulating sea-level rise impacts, including coastal erosion and plant succession across sand dunes (Bruun 1988; Feagin et al. 2005)
	Predicting spatial and temporal variation in long shore drift sand volumes (Cooper and Pilkey 2004)
	Assessing the downstream effects of large dams in American Rivers (Graf 2006)
Rocky coasts (cliffs and platforms)	Mapping factors driving cliff failure along the Oregon coastline, including tectonic uplift, subsidence, wave attack, groundwater seepage, beach and cliff geology, El Nino events, storms, and high waters (Shih and Komar 1994)
	Monitor hard rock coastal cliff erosion from a laser scanner in North Yorkshire, UK including undercutting, detachment of blocks, debris, soils, falls, slides, and flows (Rosser et al. 2005)
Coastal wetlands	Quantifying area and width reductions to coastal barriers in a delta wetland (South Louisiana) using historical maps and airborne imagery (Williams et al. 1992)
	Tracking the removal of marshes, mangroves, and tidal flats to develop fish and shrimp farms and housing in Hong Kong (Nelson 1993)
	Modeling estuarine surface elevation dynamics (Rogers et al. 2012)
Coral Reefs	Identifying sources of sediment to coral reefs (McKergow et al. 2005)
	Modeling the route of lionfish invasion in the western Atlantic and Caribbean (Johnston and Purkis 2011)
	Modeling the risk of cyclone damage to coral reefs on the GBR from tracks and wind conditions (Puotinen 2007)
Cold coasts: Permafrost, sea ice, glaciers and fjords	Simulating rock falls from paths of steepest descent, flow paths, and changes to direction of permafrost progression (Noetzli et al. 2006)
	Simulating ice-sheet response to climate change (Hanna et al. 2013)
	Modeling riverine nitrogen delivery to Vejle Fjord (Denmark) from leaching, point source emissions, soils, terrain, and ground water head elevation and nitrate decay (Skop and Sørensen 1998)
Urbanised coasts	Bathymetric and volumetric change analysis of dredged pits in Lower Bay complex, New York Harbour (Wilber and Iocco 2003)

at an accurate and unambiguous definition of a coastline is also difficult because height datums. Often there are offsets between national reference grids (e.g., the Australian Height Datum) and datums defined by gauge measurements of tidal fluctuations apparent (Hirst and Todd 2003). Given that mapping often forms a foundation for much geospatial analysis, it is important for GIS analysts to be aware of the complexities associated with describing, visualizing, and creating digital representations of the coastline.

Spatial referencing not only refers to the longitude and latitude (i.e., x and y) measurements for a given coordinate, but it also incorporates the height above a common datum (the z coordinate). There are several tidal and land datums that could potentially serve as a reference point for the definition of height measurements. When information is collected from a survey vessel on the water surface, tidal fluctuations will influence the height of that survey vessel above the seabed. This is the case when conducting a bathymetric survey of water depths using an echosounder attached to the hull of a boat. Tidal corrections must therefore be applied to any data collected from boats to account for any offsets due to the state of the tide. This is particularly important in locations where tidal ranges are large, in some locations they can be as wide as 11 m.

Most spatial analysis involves the collection of some form of in situ information, such as community census surveys or sediment samples. On shorelines with low topographic

gradients, the difference between low and high tide can represent the submergence or exposure of substantial areas of intertidal shoreline. Moreover, the accessibility of estuarine environments depends on the ability of boats to access field sites through channels. The navigability of channels depends on the depth of water. Planning and implementing fieldwork therefore requires an accurate knowledge of how tidal fluctuations interact with local coastal topography. Because weather in coastal zones is often highly changeable, the feasibility of visiting field sites further depends on the coincidence of appropriate weather conditions with a favorable tidal window. This limits the amount of field sampling that can be done, restricting the spatio-temporal range of samples collected to seasons and geographical areas that coincide with favorable fieldwork conditions. Consequently, areas that coincide with difficult conditions (i.e., the breaker zone) are notoriously under-represented in coastal fieldwork campaigns. In some situations, a feature of interest (e.g., a kelp bed or coral reef) may require a detailed population survey. The analyst may need to employ self-contained underwater breathing apparatus (SCUBA) to achieve the necessary proximity to the field site for an adequate length of time to collect data for analysis. At a regional scale, this may result in a clustered distribution of samples, governed largely by the number of dives a fieldworker can do at a given site and how far they can swim underwater before surfacing because of an empty air cylinder.

Conclusion

Despite the practical challenges of the coastal zone, GIS remains an important tool for coastal applications. The use of GIS in coastal applications continues to grow, supported by new technologies for collecting spatially referenced data, such as drones and AUVs. Nevertheless, Bartlett's emphasis on the importance of establishing the user-base for whom the coastal zone GIS is intended, and the view of the coast and its component elements that is relevant to this constituency remains useful today. This is because this operational context will have a direct bearing on the more technologically oriented questions of hardware and software selection and the overall architecture of the system. It will also define the information products expected from the system, and hence the types of data, and the processes performed on these, that are required in order to produce the desired output (Bartlett 2000, p 18).

One measure of the importance of GIS to coastal scientists is the increasing number of user-groups, web pages, spatial data infrastructures and portals (e.g., Google Oceans and NOAA's Digital Coast), online web atlases, and conferences organized around the theme. Examples of coastal GIS conferences include the International Geographic Union's Commission on Coastal Systems, the Marine Biological and Habitat Mapping Group (GeoHab), and the Working Group on Marine Cartography of the International Cartographic Association collaborative international symposium known as CoastGIS which began in 1995 and continues to hold biennial conferences. It is clear that changes in users, data, and technology have increased the sophistication and volume of meaningful spatial analysis that can be carried out in coastal environments. It is an exciting time for harnessing the benefits of GIS technology; the challenge for managing and understanding coastal environments is to think about space and spatial processes in new and creative ways.

Geographical Coastal Zonality

Dieter H. Kelletat

Institut für Geographiedidaktik, Fachgruppe der Didaktiken der Mathematik und der Naturwissenschaften Universität zu Köln, Cologne, Germany

Definition

The term “coastal zone” is used in scientific papers to describe the coastal environment or the region between the foreshore and the upper supratidal along a coastline. “Zones” in geoscience, however, are latitude-parallel belts between the equator and the poles, established in the first order by the different radiation/insolation on our globe.

Nearly all macro-patterns on Earth, which depend on climatic influences, like vegetation, soil formation, or forms of relief and inherent processes, show a zonal distribution. For the latter, including both relic and contemporary systems, this has been accepted for decades (Murphy 1968), and the term “climatic geomorphology” has therefore been established. Regarding coastal features and processes, however, these are looked upon for a long time mostly as a zonal, because cliffs, beaches, lagoons and barriers, deltas, etc. can be found in all latitudes; and rock-depending forms are regarded as a zonal, as well.

Davies (1980) established a classification of zonal coastal patterns based on prevailing wave and surf types and introduced his pioneering book on *Geographical Variation in Coastal Development*, giving an overview of the zonal coastal forms and processes, all inductively identified. Other authors then studied the global distribution of single features and their differentiation according to latitude (Kelletat et al. 2014; Martini and Wanless 2014; Perillo et al. 2009; Spalding et al. 2007; Stutz and Pilkey 2011; Wolanski et al. 2009), or the influence of humid or arid tropical climates on coastal landforms.

Almost two decades ago, a “system of zonal coastal geomorphology” was developed by Valentin (1979). This system is limited to the definition of 51 types of non-coastal landforms which were characteristic of the Wisconsin (Wurm)

glacial climato-morphogenic zones. Many of these areas were in part drowned during the postglacial sea-level rise. The glacio-eustatic drowning is in fact the only “littoral” factor in this system, but it is not a zonal process since it can be observed worldwide. In his “Atlas of Coastal Geomorphology and Zonality,” Kelletat (1995), however, applied the question of zonality in a strictly inductive sense, that is, interpreted from field evidence and areal distribution patterns, in contrast to previous deductive models. This is only one of the first steps, and a complete system of geographical coastal zonality will remain an unsolved problem, so far as the general features of coastal evolution have been firmly established. We are still far from this aim today. Some examples of zones and subzones on selected meridional transects may elucidate the problem (see also Fig. 1).

The zonality of the coasts of Europe and the Middle East is particularly influenced by two special conditions: the warming effect of the Gulf Stream in the north and the semi-enclosed oceanic basin of the Mediterranean Sea. Thus, it is only north of the Arctic Circle in the fresh or brackish waters of fiords that reach far inland and into the Baltic Sea, where the coastal influence of sea ice becomes recognizable. Between coastal freezing of the Baltic and permanent sea ice around the North Pole, another zone can be found without shore and sea-ice contacts because of the warming of the Gulf Stream around northernmost Norway (Martini et al. 2009). In hard rocks, there are only fiords and skerries affected by contemporary coastal processes. Further to the equator, the temperate coastal zone follows (Pratolongo et al. 2009).

The next important morphodynamic boundary marks the equatorial limit of frost weathering which reaches 54°N and comprises parts of the German coasts and eastern coasts of the British Isles. Thick medium-sized algae are found in the rocky littoral (*Fucus*, *Laminaria*, and others) that extends to about 46°N in France. South of 44°N latitude in the Mediterranean, calcareous algae and encrusting vermetids create youthful organic rock formations, which sometimes grow together to form trottoirs and even microatolls, particularly south of 36°N latitude. South of 38°N latitude, the occurrence of beachrock increases as do coral reefs south of 30°N in the Red Sea; while south of 28°N, the northernmost outposts of mangroves can be found at the Sinai Peninsula.

The Mediterranean may be used to illustrate problems inherent in the field methods that are commonly applied. Davies (1980) classified coasts within the zone of the “lower latitudes” and so did Valentin (1979), specifying them as “subtropical.” Davies puts the Mediterranean as well as the whole of Australia into the same zone; whereas in Valentin’s system, Australia is divided into a tropical and a subtropical zone. Both authors use the same major elements for classification, that is, the distribution of corals,

Geographical Coastal Zonality, Fig. 1 Modern geographical coastal zones of the world (Kelletat 1995)

mangroves, and beachrock. But it was only the existence of beachrock that caused the inclusion of the Mediterranean into the subtropical zone or into the zone of the lower latitudes, respectively. In the southern parts of the Australian coast, beachrock does not exist, and the subtropical zone would be erroneously shown to extend beyond the beachrock distribution area. On the other hand, the boundary of the coral reef distribution area is practically the same as that of beachrock at the east coast, whereas mangroves are found in some areas of

the south coast far beyond the usual areas of the subtropics in the Northern Hemisphere. This is an important anomaly.

Along the east coast of North America, the zonality of presently active coastal processes is more closely spaced (Kelletat 1989). The effects of sea ice on rock and beach coasts extend as far south as 46°N, and to around 40°N significant frost weathering processes can be observed. South of 35°N there are compound oyster reefs, that is, organic rock formations, together with an increasing number

of beaches with massive shell deposits. From 34°N to 30°N, hypersaline tidal flats occur in places almost completely free of vegetation (or only with microscopic plant material present), especially around the highest spring tide level. Latitude 28°N marks the poleward boundary of mangroves, 26°N that of the coral reefs. In total, there is only a separation of 20 latitudinal degrees between the coral reefs of the tropical zone and the sea-ice effects of the subpolar zone, in comparison to at least 38° on the European side of the Atlantic Ocean. These findings are in contrast with those on the coasts of eastern Australia and New Zealand. Here, the morphological impact of both sea ice and frost on the coastal environment is missing. Giant kelp (*Durvillea*, *Macrocystis*, and others) can be found as far north as 41°S, thus effectively protecting the rocky coasts from heavy surf. Serpulids and sabellariae form solid organic substrates as far north as 38°S (eastern Australia) and 37°S (New Zealand), respectively, whereas oyster reefs reach as far south as 33°S (Australia) and 37°S (New Zealand).

Within tidal limits, hypersaline tidal flats almost free of vegetation are found as far south as 42°S in New Zealand and 28°S in eastern Australia. Latitude 38°S is the southern boundary of mangroves. Just south of the limit of massive coral reefs, that is, 25°S, is the change from the tropical to the extratropical species in the rocky littoral.

The zones of giant subpolar algae and mangrove communities commonly reach within 3° latitude and sometimes even overlap. In contrast, the distance between them being 14° on the North American east coast and at least 18° in Europe to Middle East. In Florida, the northern boundary of the mangrove zone is 2° north of that of the coral zone, whereas in Australia/New Zealand it is 13°, but in North Africa/Middle East (e.g., Sinai Peninsula), the coral reefs extend 2° farther north than the northernmost mangrove, *Avicennia marina* being the species in all areas. These differences cannot properly be explained yet, mainly because the extreme and mean values of both air and water climates differ significantly at these boundary lines.

Thus, both zonal and azonal features at the coasts are manifold, zonal aspects are mainly given by climatic and biogenic parameters (at least the latter partly depends on the first), and geodynamic, structural, petrographic, or sedimentological properties dominate the azonal aspects.

Most authors have tried to define a rather simple system of coastal zonality, either by separating tropical (including subtropical) and extratropical areas or by dividing the Earth's coasts into high, mid, and low latitudes. In his synthesis of 1980, Davies characterizes these zones as follows:

High-latitude coasts: They are frozen part of the year and seasonal ice is active on the beach. Characteristics are low wave energy because of freezing and limited fetch, many pebbles at the beaches due to former glaciation and frost weathering, barriers developed well and widespread, dunes

rather limited, and tidal flats dominated by grassy vegetation. Cliffs are mainly formed by frost action; mass wasting is common, often due to permafrost decay. Further categories within high-latitude coasts may be determined by the duration of the sea-ice cover.

Mid-latitude coasts: They show high wave energy and frontal storm maxima, frequent cliffs in hard rock with quarrying and abrasion, sloping intertidal rock platforms, and weaker developed barrier systems but with partly very extensive dune areas. Biogenic effects are believed to be insignificant, except for dunes and tidal flats. A differentiation of this broad zone may be made by the limit of Ice Age glaciers deeply influencing the types of sedimentation along the coastline.

Low-latitude coasts: They are exposed to a relatively permanent approach of wind, waves, and swell, and only reduced wave energy is active. Algae and corals contribute to coastal forming, and lithification of dunes and beaches may occur. The widespread coastal sediments are of fine-grain deposits. Dunes exist in limited areas only, and rocky coasts with horizontal rock platforms are restricted. Perpendicular cliffs are very rare (except in arid areas); salt weathering is typical as well as extensive tidal woodlands (mangroves). A differentiation should be made regarding the more humid and the more arid environments.

Although the spatial distribution of some important coastal phenomena is generally known, it is difficult or nearly impossible to define the zonal limits by means of climatic data (although radiation and climate are the main sources of the zonal patterns of the Earth).

The 18 °C-isotherm of surface water in the coldest month of the year is the thermal factor which sets limits for the coral reef zone. For other coastal features, a definition is much more complicated; mangroves occur in very humid to extremely arid regions (e.g., precipitation nearly zero to thousands of millimeters per year) and within limits of low to high evaporation. Mean annual air temperatures at mangrove sites vary from about 28 °C to nearly 15 °C, those of the coldest month from more than 25 °C to only 7 °C, and coldest water temperatures from more than 25 °C to nearly 6 °C. As thermal limit for mangroves (*Avicennia* sp. or *Kandelia* sp. in Japan), several frost days with air temperatures of −4°/−5 °C may be defined, whereas the number of months with mean temperatures below 20 °C may reach from twelve to zero (as well as the number of arid months).

The climatic data for beachrock are at least as heterogeneous as for the polar limits of mangroves. They are annual precipitation from nearly zero to several thousands of millimeters, low to high evaporation, zero to twelve arid months, mean annual air temperature between 15 °C and more than 27 °C, mean temperature of the coldest month down to 7 °C, as well as water temperature, which may never reach 20 °C during the year as in Namibia. When comparing the

beachrock distribution on the islands of Oahu (Hawaii) and Madagascar, a clear relationship to the arid areas cannot be detected; microclimatic aridity may be more important than high water temperature. Both islands are situated in the core zone of beachrock distribution. In its marginal fringe like the Mediterranean Sea, beachrock in higher frequency and quality is clearly restricted to the warmer and more arid southern and eastern parts. It is only sporadic and poorly developed in its more humid and colder north and west.

In higher latitudes, the equatorial limits of giant kelp at the coasts show a similar and rather high differentiation (i.e., annual precipitation from around 300 mm to more than 1300 mm, mean annual temperatures from 7.5 °C to at least 17 °C, and the coldest month even from 13 °C down to –5 °C). The limiting factor seems to be air temperature, not exceeding a monthly average of 20°/21 °C. The average water temperature may vary from below zero to more than 15 °C. Twenty degrees centigrade seems to be lethal.

All features discussed here belong to the younger Holocene or even to contemporary decades, that is, an extremely short geologic period under a stable climatic regime. It is, however, difficult and till now partly impossible to commit to a satisfactory definition of limiting climatic conditions for most of the coastal features. In this respect, the related sciences are far from a consensus.

For example, it is difficult to define zones and subzones by coastal forms because of their multi-temporal origin, that is, from very different climates and, therefore, inherent with aspects of other zones. It may be prudent to restrict a consensus to the distribution of actual coastal processes (or those of the younger Holocene, when sea level was roughly at its present position). This will show a more homogeneous picture, comparable for all zones. A difficult, time-consuming problem that remains is detecting and evaluating processes. Due to the present state of research, we usually attempt to infer the process itself from its result (i.e., we infer cementation from the occurrence of beachrock and horizontal rock platforms from the process of salt/frost weathering or water-layer leveling, etc.). A fundamental question is, whether we should define a zone or subzone by the dominant process (if one exists) or by a combination of more than one process. Does a zone or subzone need to show only adequate processes or their forms? Should they dominate spatially, or should a zone be characterized by one process even if its geomorphological effect and importance is minimal? Additional problems include insufficient or inadequate knowledge of coastal forms and processes worldwide as well as regionally and thematically.

Conclusions

In reference to coastal features, one is faced with problems that are dominated by azonal geodynamic, geological,

structural, tectonic, petrographic, or sedimentological factors and by seawater or surf conditions, by climatic parameters, or by biospheric processes. Integration of all these categories into only one model of coastal zonality seems not to be applicable.

Knowing that contemporary coasts are formed during the last 7000 years, an extremely short timespan in geological and geomorphological times, the question arises as to whether the morphodynamic patterns now detected are representative of the last interglacial. Has the Holocene reached its climax conditions or is this still in process? An ancillary question regards zone shifts when climatic conditions changed. If it is true that coral reefs have their lethal winter temperature limit at 18 °C and giant kelp at about 20 °C in summer, a general change of 0.5 °C to 1.0 °C (which may occur within decades) would transfer their zonal limits for hundreds of kilometers. Singular and azonal events like changing ocean currents or El Niño effects may reinforce this tendency.

Being aware of the delicate balance of geomorphological zones and subzones during a given geological or climatic condition, it may be interesting to reconstruct those zones and subzones valid for former geological periods (which might have been longer lasting once they had reached their climax with certainty) and to learn from these results. On the other hand, by detecting coastal zones of former periods, it sometimes may be possible to deduce their environmental (i. e., paleoclimatological) parameters. As a synthesis, a complex world map (Fig. 1) may show the state of the art in inductive coastal zonality.

Geohydraulic Research Centers

James R. Houston
Corps of Engineers, U.S. Army Engineer Research and Development Center, Vicksburg, MS, USA

Definition

Geohydraulic research centers are research organizations that specialize in science and engineering research relating to oceans, coastal regions, and estuaries. In particular, they have laboratory facilities including flumes and basins where waves and currents can be generated and interact with coastal structures and geomorphology.

Introduction

Several geohydraulic research centers specialize in coastal science and engineering research. Some are current or former government research facilities that have been partially or completely privatized. The centers have laboratory facilities used for both research and scale-model studies to aid in project design. Some centers have developed numerical models for project design. The following summarizes capabilities of the major geohydraulic research centers.

Canadian Hydraulics Centre

The Canadian Hydraulics Centre (CHC), located in Ottawa, Canada, is a government agency and a unit of the National Research Council, Canada’s leading scientific research organization (National Research Council Canada 2017). The CHC has extensive laboratory facilities in an 8,400 m² building.

Facilities include a 14.2-by-63 m coastal wave basin with a wave generator that produces long-crested, irregular waves with significant heights up to 0.4 m, and the basin has high-efficiency wave absorbers. The basin can be configured to generate bidirectional currents and combined wave and current interactions. There is a multidirectional wave basin that is 30-by-36 m and 3 m deep with a 60-segment directional wave generator that can produce irregular waves with heights up to 0.5 m and regular waves up to 0.75 m, and the wave generators have active wave absorption. NRC has a 30-by-50 m large area basin for large 3D studies with wave generators capable of producing irregular long-crested waves with significant heights up to 0.15 m and regular waves up to 0.25 m. A second directional wave generator can produce irregular waves with significant heights up to 0.4 m. The large area basin has pumps that can generate discharges up to 1600 L/s. There is an ice tank that is 7-by-21 m and 1.1 m deep that has a towing carriage and can accommodate a wave machine. The temperature inside the chamber can be varied down to –20 °C and can produce ice of up to 0.6 m.

The NRC has a large wave flume that is 2-by-97 m and 2.75 m deep. It has a wave generator that can produce irregular waves with significant heights up to 0.75 m and regular waves up to 1.25 m; the wave generator has active wave absorption. The NRC has a steel wave flume that is 1.2-by-64 m and 1.2 m deep. It has a wave generator that can produce irregular waves with significant heights up to 0.25 m, and it has active wave absorption. There is a high discharge flume that provides a steady flow in an open channel with continuously adjustable discharge from 0–1700 L/s.

Catalonia University of Technology, Spain

The Maritime Experimental and Research Flume was built in 1992 at the Maritime Engineering Laboratory of the Catalonia University of Technology for experimentation in maritime harbors and coastal engineering (Catalonia University of Technology 2017). The flume is 3-by-100 m and 7 m deep and has a wave generator that produces irregular waves and regular waves with maximum heights of 1.6 m. There is a bidirectional pumping system that can pump 2000 L/s.

Centre for Marine and Renewable Energy, Ireland

The Centre for Marine and Renewable Energy (MaREI), Ireland, is the marine and renewable energy research and development organization supported by the Science Foundation Ireland (Centre for Marine and Renewable Energy 2017). The Environmental Research Institute of the University College of Cork coordinates MaREI efforts with 130 researchers working across six academic institutions and collaborating with over 45 industry partners. MaREI has a facility for small- to medium-scale laboratory testing of ocean and maritime systems and a 2600 m² facility that houses four wave tanks.

MaREI's ocean basin is 18-by-25 m and 1 m deep with a wave generator that produces irregular waves with a peak significant wave height of 0.16 m, peak period of 1.4 s, and maximum height of 0.32 m. Its deep ocean basin is 12-by-35 m and 3 m deep with a wave generator that can produce significant wave heights of 0.6 m, peak period of 2.7 s, and a maximum wave height of 1.1 m. Its wave and current flume is 3-by-28 m with a depth of 1.2 m that can study unidirectional waves and wave-current interaction. Its wave generator can produce a significant wave height of 0.16 m, a peak wave period of 1.5 s, and a maximum wave height of 0.35 m, and the facility can generate currents of 1500 L/s. There is a wave flume for students that is 0.75-by-15 m and 1 m deep.

Coastal and Hydraulics Laboratory, United States

The Coastal and Hydraulics Laboratory (CHL) is in Vicksburg, Mississippi, USA, and was formed in 1996 through a merger of the Hydraulics Laboratory founded in 1929 (originally the Waterways Experiment Station) and the Coastal Engineering Research Center founded in 1930 (predecessor organization was the Beach Erosion Board) (Coastal and Hydraulics Laboratory 2017). CHL is part of the seven-laboratory complex of the Engineer Research and Development Center (ERDC) of the Corps of Engineers that includes seven research laboratories in four states. The ERDC has 2,200 employees, including 250 in CHL.

CHL has the largest coastal and hydraulic laboratory complex in the world with about 140,000 m² of laboratory facilities under roof. About a quarter of these facilities are used for coastal engineering research and scale modeling with the remainder used for hydraulic engineering research and scale modeling. CHL has several wave flumes, all with irregular wave generators including the following: 2-by-105 m, 1.4 m water depth, and 0.45 m wave height; 3.5-by-80 m, 1.4 m water depth, and 0.45 m wave height; 3-by-65 m, 1 m water depth, and 0.5 m wave height; 1.5-by-65 m, 1 m water depth, and 0.5 m wave height; 0.6-by-60 m, 1 m water depth, and 0.6 m wave height; 1-by-45 m, 0.6 m water depth, and 0.2 m wave height; and 1-by-45 m, 0.6 m water depth, and 0.2 m wave height. CHL's L-shaped facility tests 3D stability of structures such as breakwaters and is 15-by-75 m at the wave generator and 25 m wide at the testing end. It operates with water depths up to 1.5 m and uses a wave generator with a wave board that is 4 m high and 15 m wide and produces 0.6 m waves.

CHL has about 30,000 m² of covered laboratory space for 3D wave basins used for studying waves in harbors, movable-bed modeling, coastal processes, wave interaction with ships and other floating structures, and other coastal engineering applications. Large remote-controlled scale-model ships (e.g., container ships) measuring about 7 m in length can be employed to test ship maneuverability in irregular directional seas with currents and wind. Long-wave harbor resonance is tested in a facility with a wetted area of over 4,000 m² and 14 irregular wave generators, each approximately 5 m long, which generate waves with periods from 1 to 10 s.

Its Long Shore Transport Facility is a wave basin that is 30-by-50 m (expandable to 80 m) and 1.4 m deep that is used to study longshore currents and sediment transport. Wave generators produce regular or irregular waves with heights up to 0.4 m, periods of 1.0–3.5 s, and angles up to 20° from shore normal. A longshore current recirculation system has 20 independent upstream and 20 downstream flow channels each with a turbine pump that discharges up to 75 L/s. The system controls cross-shore distribution of wave-driven longshore currents and recirculates currents from downstream to upstream. Downstream flow channels have sediment traps that record sand accumulation and a dredging system that recirculates sand collected in the traps to the upstream end.

CHL's ESTEX Hyperflume facility is used for conducting unsteady, nonuniform flow and sediment transport research and is 15-by-18 m, 3 m deep and connected to an 18-by-107 m and 1.2 m deep basin and a parallel 3-by-122 m and 3 m deep basin. There is a 15 million liter full-scale test facility to study levees and develop new methodologies to assist in flood-fighting efforts. CHL's has 3D ship and tow simulators for design of navigation channels that include a complete full-scale ship bridge and real-time visualization and can simulate ships, tows, and small crafts.

The Coastal Modeling System developed by CHL is a suite of coupled 2D numerical models for simulating waves, hydrodynamics, salinity and sediment transport, and morphology change. CHL's Beach-fx model evaluates the physical performance and economic benefits and costs of shore protection projects. CHL's 2D and 3D Surface-Water Modeling System and Groundwater Modeling System are now offered through the private sector company Aquaveo.

Danish Hydraulics Institute, Denmark

The Danish Hydraulics Institute (DHI) is an engineering consultant firm headquartered in Denmark with 30 offices throughout the world, largely involved in hydraulic and hydrological modeling software (Danish Hydraulics Institute 2017a, b). It was founded in 1964 by the Technical University of Denmark and, although independent, is associated with the Danish Academy of Technical Sciences. It has an offshore wave basin in Hørsholm, Denmark, that is 20-by-30 m with a depth of 3 m. The basin has a wave generator with 60 individually-controlled flaps that can produce short-crested irregular 3D waves and swell. Wind can be produced by fans and pumps can be produced currents. There is a shallow basin that is 25-by-35 m with a depth of 0.8 m and a multidirectional segmented irregular wave generator, currents that be generated by external recirculation of water, and wind generated by fans. The facility has a flume that is 0.74-by-28 m with a depth of 1.2 m.

DHI has a suite of 1D, 2D, and 3D numerical models under its MIKE umbrella. For example, MIKE 3 is a 3D modeling system that simulates flows, cohesive sediments, water quality, and ecology in rivers, lakes, estuaries, bays, coastal areas, and seas in three dimensions. MIKE SHE is an integrated hydrological modeling system for surface and groundwater flows.

Deltares, Netherlands

Deltares is a major technological institute in the Netherlands that focuses on river basins, coastal regions, and river deltas (Deltares 2017a, b). Delft Hydraulics, a famous hydraulic laboratory founded in 1927, became a part of Deltares in 2008. Deltares has over 800 employees located in Delft Utrecht in the Netherlands.

Hydraulic/coastal facilities at Deltares include its Atlantic Basin, built in 2009. This is a multifunctional facility with a total size of about 650 m², in which waves and tidal currents can be simulated. The basin is 8.7-by-75 m with a height of 1.3 m, allowing a water depth of 1 m. In the test section, it has a closable pit of 130 m² and a depth of 0.5 m to allow modeling of a mobile bed. A sediment sieve is constructed

at the downstream side for the collection of lightweight material in morphological tests. The wave generator consists of 20 independently-controlled wave paddles that make it possible to produce oblique waves with directional spreading and with a maximum significant wave height of 0.25 m at a period of 2 s and a maximum wave height of 0.45 m. The wave generator has automatic reflection compensation. A current can be generated via a pumping system either following or opposing the waves with a maximum pumping capacity of 3000 L/s. Depending on the project-specific needs, the basin layout can be modified, for example, by building wave-damping beaches or sluice gates.

The Pacific Basin is a multifunctional wave-current basin that is used for coastal- and offshore-related projects in which 3D effects are important, such as testing breakwater heads and foundations of offshore structures. The wave basin is 22.5-by-30 m and has a basin height of 1.25 m, allowing a maximum water depth of 1 m with a minimum depth of 0.25 m. The wave generator has a width of 14 m and a wave board height of 1.2 m. It can generate waves with a frequency range of 0–2 Hz, a maximum significant wave height of 0.21 m at a wave period of 1.9 s, and a maximum wave height of 0.4 m. It has a pumping system with one-directional flow and a capacity of 1800 L/s.

The Scheldt Flume is a 1-by-110 m wave flume with a depth of 1.2 m that is used for studies such as breakwater armor stability and wave impact loading. The flume has wave generators at both sides that enables one side to be used for wave generation and the other for wave dissipation. The wave generators can produce significant and maximum wave heights of 0.25 m and 0.4 m, respectively. At one side of the flume, a pumping system is installed that has a maximum pumping capacity of 600 L/s.

The Delta Basin is a 50-by-50 m wave basin with a water depth of 1 m that is equipped with two multidirectional irregular wave generators with a total length of 66.4 m, placed at a right angle to each other. The wave generators can produce both periodic and irregular long-crested or short-crested waves. Both wave generators are equipped with active reflection compensation. Maximum wave heights and significant wave heights are 0.6 m and 0.25 m, respectively.

The Delta Flume is 5-by-291 m and 9.5 m deep. Its wave generator produces maximum wave heights and significant wave heights of 4.5 m and 2.2 m, respectively, with wave periods of 1–20 s. The facility makes it possible to test at full scale the effect of extreme waves on dikes, dunes, breakwaters, and offshore structures.

The Deltares Intake and Outfall Structure (IOS) basins 1 and 2 can be used for model testing of most hydraulic structures. The large IOS-1 basin is 12.5-by-20 m and allows for modeling cross flows of channels or rivers. The smaller IOS-2 basin is 6-by-16 m and allows higher water levels, so that smaller designs can be studied on a larger scale. There are

three pumping stations with a capacity of 1000 L/s to pump water between the reservoir and the flume, making it possible to produce high waves and at the same time to simulate variations in the water level caused by storm surges and tides.

The AlphaLoop is a facility for investigating a wide range of multiphase flows in pipeline systems. The AlphaLoop allows for single-phase (water), two-phase (water and air), and three-phase (water, air, and sediment) experiments.

Deltares has its Delft3D software that provides 3D computations for coastal, river, lake, and estuarine areas. It calculates flows, sediment transport, waves, water quality, morphological developments, and ecology. In addition, Deltares has the software, XBeach, a 2D model for wave propagation, long waves and mean flow, sediment transport, and morphological changes of the nearshore area, beaches, dunes and back barrier during storms.

Flanders Hydraulics Research, Belgium

The Flanders Hydraulics Research is a division of the department of the Flemish Ministry of Mobility and Public Works, Belgium (Flanders Hydraulic Research 2017). It was founded in 1933 as a part of the Antwerp Maritime Services, became part of the Ministry of Public Works and the Waterways and Marine Affairs Administration in 1945, and in 2006 was integrated into the Flemish Ministry of Mobility and Public Works.

Facilities include a wave flume that is 4-by-70 m with a depth of 1.4 m. The wave generator can produce waves of height 0.65 m at a depth of 0.9 m. There is a small flume of length 0.7-by-3.17 m and depth of 0.86 m that has a wave generator that can produce 0.4 m height waves in a water depth of 0.6 m.

A 3D facility is 12.2-by-17.5 m with a depth of 0.45 m and a testing area that is 10-by-12 m. The facility has an adjustable water level and can be used with or without a moveable bed to test wave overtopping, wave intrusion into harbors, stability of beaches, and wave-current interaction. The facility has a moveable multidirectional irregular wave generator that is 12 m wide and can produce short- and long-crested waves. A pump with a maximum flow of 175 L/s can create current velocities up to 0.3 m/s both in the direction of the wave movement and against this direction.

A sloping bed current flume is 0.5-by-34.8 m with a depth of 0.76 m and can be used to calibrate measurement devices such as velocimeters. A multifunctional test basin is used for research on locks (design of filling and emptying systems, hawser forces), controlled inundation areas with reduced tide (design of inlet and outlet sluices, submersible dikes), and hydraulic characteristics of structures. It is 9.8-by-19 m with a depth of 1 m and can be subdivided in half. One half is operated as current flume with a pump capacity of 500 L/s

and maximum upstream water depth of 1.45 m. The other half is for lock modeling with a pump capacity of 120 L/s and water depths of 0.5–1.2 m. There is a 52 m² test area. Another current flume that can study flow patterns and head losses associated with weirs, fish passage, and other phenomena is 2.4-by-56.2 m with a depth of 1.15 m. Pumps can generate a maximum flow of 600 L/s.

A towing tank to study ship behavior in confined areas is cooperated with Ghent University. It is 7-by-88 m (67 m of the 88 m can be used for experiments) and maximum water depth of 0.5 m. Ship models are usually about 4 m (scale of 1:50–1:85). A wave generator can generate both regular and irregular waves to study the vertical motion of a ship under the influence of waves. An auxiliary carriage can move a second ship model on a straight trajectory to determine forces exerted on a ship by ships passing or overtaking it.

For studies of the Port of Zeebrugge, there is a scale model with a total area of 2000 m², horizontal scale of 1:300, vertical scale of 1:100, velocity scale of 1:10, time scale of 1:30, and discharge scale of 1:300,000. The model simulates a coastline of 15 km and extends a simulated 10 km into the ocean. The model has been used to study large cross currents at high water that limit inbound container and liquefied natural gas carriers to a window of passage of 4–6 h. In addition, it has been used to study methods to reduce dredging costs.

HR Wallingford, United Kingdom

HR Wallingford is an independent civil engineering and environmental organization in the United Kingdom with offices around the world (HR Wallingford 2017). It has the UK designation of a Scientific Research Association with company members that include many UK organizations including the British Ports Association, Association of Consultants and Engineers, Institution of Civil Engineers, and Royal Academy of Engineering.

HR Wallingford facilities are housed in buildings of 14,400 m². It has six wave basins ranging in size from 25-by-32 m to 32-by-75 m. Its largest wave basin is one of the largest unobstructed hydraulic test tanks in the world. Wave generators have active wave absorption and produce waves up to 0.25 m in height in water depths up to 0.8 m. A 27-by-55 m wave-current basin can generate uni- or bidirectional currents of up to 1200 L/s. There are two wave flumes that are 1.2-by-45 m and with operating depths of up to 1.5 m. There is a flume that is 1.8-by-100 m with an operating depth of up to 1.8 m. The flumes can produce regular and irregular waves with significant wave heights up to 0.3 m.

HR Wallingford is a member of a consortium of organizations including Artelia (formerly Sogreah), France; Bundesanstalt für Wasserbau, Germany; and Centre d'Etudes Techniques Maritimes et Fluviales, France that manages

TELEMAC-MASCARET, an integrated suite of software for free-surface flow (Telemac-Mascaret 2017).

Kajima Research Institute, Japan

The Kajima Research Institute (KRI) was established in 1949 and is in Tobitakyu, Chofu, Tokyo, Japan (Kajima Research Institute 2017). It is a research institute of Kajima Corporation, a private sector construction company.

KRI has a laboratory facility built in 1975, that is, in a 2,870 m² building. It houses a wave basin that is 20-by-58 m and 1.6 m deep, and its directional irregular wave generator can produce waves up to 0.6 m in height with wave periods from 0.5 to 5 s. The wave generator has active wave absorption. The facility also has a tsunami wave generator, and the basin is equipped to generate tides. KRI has a large wave flume that is 2-by-62 m and 2 m deep that is used to test wave forces on structures and other 2D phenomena. Its wave generator can produce waves up to 0.6 m in height, absorb reflected waves, and generate low-frequency, arbitrarily shaped wave forms to study tsunamis. There is a medium-size wave flume that is 0.7-by-60 m and 1.5 m deep, and its wave generator can produce irregular waves with maximum heights of 0.5 m and absorb reflected waves. Currents with a maximum discharge of 200 L/s can be generated in the flume.

Ludwig-Franzius-Institute, Germany

The Ludwig-Franzius-Institute for Hydraulic, Estuarine, and Coastal Engineering was founded in 1916 at the Leibniz University of Hanover, Germany (Ludwig-Franzius-Institute 2017). It has a 16,800 m² covered laboratory facility housing the second largest wave flume in the world that is 5-by-307 m with a depth of 7 m and a wave generator with active wave absorption that produces regular and irregular waves with a maximum wave height of 2 m. It has a 3D wave basin that is 25-by-40 m with a depth of 1 m and a directional irregular wave generator with 72 individual wave boards that can produce maximum wave heights of 0.47 m and has an active wave absorption system. In addition, the facility can generate currents of 300 L/s. It has a second wave flume with a length of 2.2-by-110 m and depth of 2 m and an irregular wave generator that can produce maximum wave heights of 0.35 m.

Manly Hydraulics Laboratory, Australia

The Manly Hydraulics Laboratory (MHL) is in Manly Vale, a suburb of Sydney, Australia (Manly Hydraulics Laboratory 2017). MHL was established in 1944 to provide specialist services relating to water, coastal, and environmental

challenges. It is now a business unit within the government and corporate service division of the Department of Finance, Services and Innovation.

MHL has 2,230 m² of covered experimental space and 3,530 m² of open-air experimental space. It has a 1-by-30 m flume with a depth of 1.8 m and adjustable floor and an irregular wave generator, an 0.6-by-11 m tilting flume with glass panels that is 0.8 m deep, and a 20-by-30 m wave basin that is 1 m deep wave basin with an irregular multidirectional wave generator.

Norwegian Marine Technology Research Institute, Norway

The Norwegian Marine Technology Research Institute (MARINTEK) performs research and development for companies in the field of marine technology (SINTEK 2017). It is part of SINTEK, the largest independent research organization in Scandinavia that is headquartered in Trondheim, Norway. The Norwegian University of Science and Technology is a public research university in Norway. It has a hydraulic laboratory at its campus at Trondheim University that has an ocean basin that is 50-by-80 m with a depth up to 10 m and maximum current velocities of 0.2 m/s at a 5 m water depth. It has a wave generator that can generate regular waves with a maximum height of 0.9 m and wave periods greater than 0.8 s and irregular waves with a maximum significant wave height of 0.5 m. A second wave generator has 144 individual wave boards and can generate regular waves with a maximum height of 0.4 m with wave periods greater than 0.6 s and multidirectional irregular waves with a significant height of 0.2 m and wave period greater than 0.7 s.

Oregon State University, United States

Oregon State University has the largest wave flume in North America (Oregon State University 2017). It is 3.7-by-104 m and has a depth of 4.6 m. The flume has a maximum water depth of 2 m for studies of tsunamis and 2.7 m for wind and storm waves. Its wave generator can produce regular, irregular, or user-defined waves such as tsunamis and has a wave period range of 0.8–12 s. It can produce a maximum wave height of 1.7 m at a wave period of 5 s or a 1.4 m tsunami.

Queen's University, Canada

The Coastal Engineering Research Laboratory of Queen's University was built in the late 1960s in Kingston, Ontario, Canada, and has a covered area of 1750 m² (Queen's University 2017). The facility is operated by the Department of Civil

Engineering and is the largest hydraulic laboratory in Canada. The Laboratory has a coastal model basin that is 21-by-21 m and equipped with an irregular wave generator. Tides and currents can be reproduced in the basin and a sand bed can be used in experiments. The laboratory has an oscillating water tunnel for research on boundary layers, forces on structures, and other problems. It has three 45 m wave flumes, two of which are equipped with irregular wave generators and one with a regular wave generator.

Scripps Institution of Oceanography, United States

The Scripps Institution of Oceanography located in La Jolla, California, USA, has a hydraulic laboratory with facilities to address coastal and oceanographic research (Scripps Institute of Technology 2017). The facilities are in a building with 31-by-46 m.

A flume has interior dimensions of 2.39-by-44.5 m and is 2.44 m deep. Windows, the longest being 5.5 m, allow optical access from the flume side. The wave generator can produce a maximum wave height of 0.45 m at 5 s. An open-circuit wind tunnel produces variable wind velocities ranging from 0 to 16 m/s with a 1.5 m water depth. The wave generator can produce a maximum wave height of 0.6 m. An open-circuit wind tunnel produces variable wind velocities ranging from 0 to 16 m/s. There is a flume that is 0.5-by-33 m with a 0.5 m water depth, a wave generator that can generate 0.25 m waves, and a reversible flow system that can generate a maximum flow of 41 L/s.

Sogreah, France

Sogreah is a company founded in 1923 with hydraulic laboratory facilities in Grenoble, France (Artelia 2017). It merged in 2009 with the construction management company, Coteba, to form Artelia. Its hydraulic laboratory facilities include 11,000 m² of physical model space under roof and 3200 m² of outside space on the outskirts of Grenoble. It has five wave tanks including a 40-by-40 m multidirectional irregular wave generator, three wave flumes, and 1600 m² for scale-model testing. Artelia is a member of the consortium including HR Wallingford that manages TELEMAC-MASCARET, an integrated suite of software for free-surface flow.

Tianjin Research Institute, China

The Tianjin Research Institute of Water Transport Engineering in Tianjin, China, is part of the Ministry of Transport (Zhang and Geng 2015). It built the largest wave flume in

the world in 2014. The flume is 5-by-450 m and 8–12 m deep. Its wave generator can produce a regular wave with a maximum height of 3.5 m. Currents can be produced with a maximum velocity of 1 m/s and a flow rate of 2000 L/s in the forward direction and 1400 L/s in the reverse direction. A sand bed is in the test area of the flume and is 5-by-100 m and 4 m deep. The facility will initially be used for research on scale effects in models, stability of breakwaters and sea walls, breakwater overtopping, structure foundations, and sediment issues.

University of Delaware, United States

The University of Delaware's Center for Applied Coastal Research located in Newark, Delaware, USA, has an Ocean Engineering Laboratory built in 1981 that is among the largest university laboratories in the United States (University of Delaware 2017). It has a two-story 30-by-38 m facility for laboratory experiments in coastal and ocean processes. Its wave basin is 20-by-20 m and 1.1 m deep and has a directional irregular wave generator that has 34-flap individually programmed wave paddles. It has a wave tank that is 0.6-by-33 m and 0.76 m deep. Its wave generator can produce regular and irregular waves, and water can be recirculated in the tank and produce a current of 0.3 m/s. A recirculating Armstrong flume is 0.4-by-0.6 m deep and used to generate hydraulic jumps. The center also has a sand beach wave tank that is a towing and wave tank with a cross section of 1-by-2 m.

Summary

There are major geohydraulic research centers in 14 countries in North America, Europe, Asia, and Australia. The number of scale-model hydraulic facilities has decreased somewhat over the past decade as numerical models have been replacing some of the facilities. However, new facilities have been built such as the largest flume in the world that was completed in 2014 in China. The facilities aid in understanding ocean, coastal, and estuarine processes and evaluate the efficacy plans to expand harbors, restore beaches, increase coastal resiliency, and promote sustainable development.

Geomorphology and Sea Level

Niki Evelpidou

Faculty of Geology and Geoenvironment,
National and Kapodistrian University of Athens,
Athens, Greece

Definition

Geomorphological sea-level indicators can be defined as geomorphological features, erosional or depositional, which may be used to obtain accurate information regarding the position of relative sea level. In order to increase both their accuracy and their significance, it is best to be used together with other sea-level indicators, i.e., to determine their chronology.

Introduction

The geomorphology and sedimentology of the contemporary coasts are owed to the sea level changes during the Holocene and to a lesser degree during the Pleistocene. Environmental conditions, e.g., the prevailing hydrodynamics, coastal topography, and sediment availability, influence the nature of the coast and its response to sea-level rise. Environmental change may alter geomorphic process rates and process regimes in coastal landscapes. The reconstruction of past coastal landscapes, as well the reconstruction of past sea levels, ultimately allows us to thoroughly understand the palaeoenvironment.

There are a number of coastal geomorphological features used as sea-level indicators, with variable accuracy. In general, they may be the result of either erosional or depositional processes. Depositional features include beachrocks and marine terraces, while erosional include notches, sea caves, potholes, and tafoni, among others. One of the advantages of depositional sea level indicators is that they may provide datable material, while erosional features are generally inadequate for dating former sea levels.

Marine Terraces and Benches

A marine terrace is a coastal landform, a relatively flat, horizontal, or gently inclined surface of marine origin, most often an old abrasion or denudation platform, which has been uplifted generally by tectonics or eustasy (Fig. 1). It is usually bounded by a steep ascending slope on one side and by a steeper descending slope on the opposite side and it lies above or below the current sea level. A terrace may be several hundred meters wide and may reach as much as 600 m above present sea level, like at Huon Peninsula, Papua New Guinea.

Geomorphology and Sea Level, Fig. 1 Marine terraces owe their formation to the combined effect of eustatic and tectonic processes

Marine terraces owe their formation to the combined effect of eustatic and tectonic processes (Pirazzoli 2007). The study of such landforms contributes significantly to Quaternary stratigraphy, the reconstruction of eustatic sea level changes, and tectonic movements (e.g., Santoro et al. 2013).

There are various methods of dating marine terraces: from correlation or by direct dating of related materials including ^{14}C radiocarbon (for Holocene and Postglacial terraces); $^{230}\text{Th}/^{234}\text{U}$, ESR, OSL (for Pleistocene terraces); or by identifying guide fossils, such as *Strombus bubonius* in the Mediterranean for the Tyrrhenian stage. Recently, the cosmogenic nuclides method has also been used through ^{10}Be and ^{26}Al cosmogenic isotopes produced in situ. Terraces of the Marine Isotope Stage (MIS) 5 to MIS 13 may be identified, mapped, and dated with this method.

From a geomorphological point of view, the best sea-level indicator of a terrace is the limit between the upper part of the terrace and the adjacent cliff base, especially if it is marked by a notch, because it can be correlated with the corresponding eustatic transgression (Pirazzoli 2007).

Marine Notches

Tidal Notches

Recently, the term “tidal notch” is used as a sea-level indicator for marks of coastal erosion in the scientific literature. Particular profiles of bioerosion that undercut sheltered vertical

cliffs of carbonate rocks in the intertidal zone are called tidal notches, with a vertex at the biological mean sea level (BMSL), the limit between the midlittoral and infralittoral zones (see Laborel and Laborel-Deguen 2005). In the Mediterranean, a microtidal area, the BMSL corresponds, with an accuracy of ± 10 cm (Evelpidou and Pirazzoli 2016), to the local mean sea level (MSL). The most common profiles of bioerosion in tidal notches are recumbent V-shaped or U-shaped forms. The inward depth, D , of the maximum convexity, B , (vertex) is located near MSL. Above the base of the notch the notch floor, C , is flat if the tidal range is small (Fig. 2).

In a moderately exposed site, continuous wave action may splash sea water onto the roof (A). Thus the top of the notch will be shifted upward, even above the highest tide level. In this case the height becomes larger, while the base remains at the lowest tide level or slightly below it. The height (H) of the notch, therefore, increases with exposure; however, in very exposed sites, tidal notches may be lacking completely. If, after some deepening of the notch, the roof collapses, a new notch similar to the preceding one will form further inside the cliff.

Other marks of coastal erosion, due to variable rock resistance and nature or due to changes in erosional efficacy may be superimposed on the theoretical tidal notch profile. They can even modify the genetic identification of the notch. In such cases, the notches are often discontinuous; the notch base or part of the erosional profile has disappeared, dissolved by fresh water arrivals. Often, the presence of organic

Geomorphology and Sea

Level, Fig. 2 The basic characteristics of a tidal notch profile: A, C the notch roof and floor, respectively, B the vertex, D the inward depth, and H the height

accretions, developed on the notch floor, may transform the initial tidal notch into a surf notch (Pirazzoli 1986). In this case, its use as a sea-level indicator will depend on the species forming the organic accretions, rather than on the shape of the notch.

Tidal notches are of special interest, because they provide information regarding sea level changes, as well as tectonic displacements. More specifically, the profile of a tidal notch provides information on how long the mean sea level has remained constant at the vertex position (maximum retreat point), as well as on the speed of RSL change (e.g., gradual or rapid) (Pirazzoli 1986; Evelpidou et al. 2011). Tidal notches are considered as excellent sea-level indicators and have often been used in the Mediterranean and elsewhere to decipher relative sea level changes and vertical tectonic movements (e.g., Evelpidou et al. 2011; Evelpidou and Pirazzoli 2014, among many others).

Bioerosion Rates

Several estimates of erosion rates that are attributed to biologic activity have been noted in the literature (e.g., Pirazzoli 1986, Table 1; Evelpidou and Pirazzoli 2016 and references therein). In carbonate rocks the deepening of the notch profile is concentrated biologically in the midlittoral zone, where eroding Cyanobacteria, patellaceous gastropods (limpets) and chitons are abundant (Laborel and Laborel-Deguen 2005). Detailed estimations on rates of surface retreat in an intertidal notch show a range varying from less than 0.1 mm/a to 5 mm/a, depending on lithology, location and probably duration of bioerosion (for references, see Pirazzoli 1986; Evelpidou et al. 2011; Moses et al. 2015; Evelpidou and Pirazzoli 2016). Bioerosion rates reported from the Mediterranean generally vary between 0.2 and 1 mm/a (e.g., Laborel and Laborel-Deguen 2005; Evelpidou and Pirazzoli 2016).

Modification of a Tidal Notch Due to Relative Sea-Level Changes

If a movement of the relative SL occurs, the notch profile will be modified. In the case of emergence due to relative sea level fall, several results are possible (Fig. 3). A sudden emergence (e.g., coseismic) greater than the tidal range is a unique case, in which, the notch, completely emerged, is preserved from further marine modification while a new notch develops lower, in the new intertidal zone. A rapid relative SL fall with a vertical displacement smaller than the tidal range will allow only the notch roof to be preserved, while the floor is attacked and degraded from the new low-tide level; in this case, the height of the notch will increase.

If a rapid relative sea level change occurs faster than the local bioerosion rate, then the following cases may be found: In the case of relative sea level fall, the tidal notch will be preserved completely emerged; but in the case of sea-level rise two cases are possible: (1) if the SL rise is greater than the local tidal range, then the tidal notch will be preserved completely submerged (2) if the SL rise is smaller than the local tidal range, the tidal notch will be modified because its vertex will be displaced upward proportionally to the vertical displacement.

If multiple sudden vertical movements occur, successive overlapping indentations will produce so-called ripple notches (Fig. 4). A gradual slow rate of emergence (e.g., 1 mm/year) or a gradual SL oscillation will result in a symmetrical notch profile; however, the height of the profile will adapt to the amplitude of change. A gradual emergence, following a period of stable SL, will cause only the floor of the notch to be modified. In the case of a gradual emergence between two periods of stable SL, the notch will assume a reclined W-shaped profile. Many combinations of movements

Geomorphology and Sea

Level, Fig. 3 In case of emergence due to relative sea level fall, the tidal notch may be preserved uplifted and depending on the conditions different profile types will be developed

**Geomorphology and Sea**

Level, Fig. 4 Ripple notches may develop if multiple sudden vertical movements occur in a relatively short time period

leading to submergence instead of emergence are possible. Very recent emergence may be indicated by limpet and chiton marks with an abrupt limit below the roof.

In the case of gradual submergence at a rate smaller than the bioerosion rate, the vertex of the notch profile will be displaced downward and the height of the notch will increase (Fig. 5).

A special case is gradual subsidence occurring at a rate exceeding the local bioerosion rate, as during the last two centuries; according to recent studies (e.g., Kemp et al. 2011, and references therein) the global sea level has risen by 6 cm during the nineteenth century and by 19 cm in the twentieth century, at an average rate of 2.1 mm/year. With such a sea-level rise, greater than the tidal range (e.g., in

Geomorphology and Sea

Level, Fig. 5 In case of gradual submergence at a rate smaller than the bioerosion rate, the height of the notch vertex will increase

most of the Aegean Sea, this rate exceeds the bioerosion rate), the consequences will be similar to those of a coseismic uplift of the same amount, i.e., the submergence of the tidal notch that was developing up to the nineteenth century (that has been called “modern”), while no new tidal notch will be developing near the present sea level (Evelpidou et al. 2012).

Other Types of Marine Erosion Notches

Solution Notches

It is well known that fresh water arrivals may cause phenomena of dissolution on limestone rocks. According to Higgins (1980), solution notches in calcareous rocks are only present near coastal springs, where surface seawaters are diluted locally by freshwater. In the case of a relative sea-level rise along with fresh water arrivals on a carbonate coast, the profile of a tidal notch will initially start its development, but dissolution will soon occur, tending to make the floor of the tidal notch disappear, while the roof of the notch remains. The continuation of sea-level rise will result in an upward gradual displacement of the notch roof, which will remain isolated, testifying to the former presence of a tidal notch. In a paper examining tidal notches in the Gulf of Corinth (Greece), Evelpidou et al. (2011) have proposed to call “visor” such remnants of a tidal notch by dissolution.

Structural Notches

Wave erosion exerted on weaker layers of a cliff or of a rock formation may leave a notch-like mark that is called structural notch; such features are not related to sea level and, thus, are not used as sea-level indicators.

Surf Notches

When water turbulence increases, organic incrustations tend to develop on the floor of a tidal notch (Pirazzoli 1986) and to protect from further erosion and a bench (surf bench) will begin to form. In these cases, the tidal notch will become a surf notch and its accuracy as sea-level indicator will depend on the species of the organic accretion. In the Eastern Mediterranean such surf benches are often called “trottoirs,” which are found usually not more than 0.2–0.4 m above MSL (Pirazzoli 2005).

Abrasion Notches

Pebbles or sand transported by waves may cause abrasion on a notch profile, producing a polished surface. In these cases the notch can be called an abrasion notch. According to Kelletat (2005), these types of notches are occasionally found nearby coastal caves in areas of less resistant rocks.

Wave-Cut Notches

The term wave-cut notch is sometimes found in the coastal literature. However, such vague term may refer to any type of marine notches.

Beachrocks

Beachrocks are defined as hard sedimentary formations, which consist of coastal sediments (sand, pebbles, etc.), lithified relatively quickly through the precipitation of carbonate cement (Fig. 6). Field surveys and laboratory experiments (e.g., Vousdoukas et al. 2007 and references therein) have shown that lithification is rapid, ranging from a few years to decades.

Beachrocks are found mainly in the Mediterranean, the Caribbean, on tropical and subtropical Atlantic coasts, as well as in the atolls of both the Pacific and Indian Ocean. As beachrocks are often found near sea level, it was considered they are forming in the intertidal zone and that their exposure is owed to coastal retreat.

Beachrocks typically form in the interface between seawater and meteoric water, i.e., the mixing zone. In particular, beachrock cements consist of metastable carbonate phases (e.g., Vousdoukas et al. 2007 and references therein): high magnesian calcite (HMC) or aragonite, depending on the physicochemical factors of the diagenetic environment.

Conflicting theories about the formation zone of beachrocks may be found in the literature. Some authors suggest their development in the intertidal zone (e.g., see Vousdoukas et al. 2007 and references therein), while Kelletat (2006) suggests a supratidal genesis in the spray zone, since beachrocks in microtidal areas often present a thickness much greater than the tidal range. Beachrocks are frequently

used for the study of coastal evolution, as well as for the relative sea level changes both in the Mediterranean and elsewhere (e.g., Karkani et al. 2017).

Beachrocks Formation

The cement of beachrocks is indicative of their development zone, a chemically active zone. The sedimentary layer, which is closest to the aquifer, is cemented firstly and faster, while surfaces where the microbes are active are preferable.

In microtidal or a-tidal areas, beachrocks may be characterized by small thickness, corresponding to the seasonal variation of the mean sea level (MSL), while in areas with higher tidal range, such as Australia, along the Great Barrier Reef, the thickness of the cemented layers may exceed 3 m.

Diagenesis takes place below the surface, responding to changes of the height of the aquifer, the temperature, or the pressure (Mauz et al. 2015). It involves processes, such as dissolution, re-precipitation, and re-crystallization to ultimately result in chemical stability. The study of the mineralogy and microstratigraphy of the cement can provide information regarding the formation zone of beachrocks, which is particularly valuable when beachrocks are used as sea-level indicators (Mauz et al. 2015). For example, high magnesian calcite (HMC) and aragonite are developed in circumgranular rims in meniscus fabric in the vadose environment, while in the meteoric zone they are developed in symmetrical crusts (Mauz et al. 2015).

Geomorphology and Sea

Level, Fig. 6 Beachrocks represent former shorelines and are often used to understand sea level fluctuations together with other sea-level indicators

Beachrocks as Indicators of Sea Level Changes-Concerns

Altitude Relationships

Beachrocks have proven to be particularly useful when no other sea-level indicators are present or when they are combined with other available indicators. The mineralogy and the morphology of the cement are indicative of the diagenetic environment, so the examination of microstratigraphy, and the characteristics of cement allow the determination of the spatial relationship between the coastline and the formation zone of the beachrock (Mauz et al. 2015).

Recently, Mauz et al. (2015) proposed a more reliable methodology for using beachrocks as sea-level indicators by associating the cement and the sedimentary structures with a particular tidal zone and assigning an error to the indicator, depending on the aforementioned characteristics. As already noted, beachrocks with large thickness have been observed in microtidal areas, so when they are used as sea-level indicators, without mineralogical information, a relatively large error must be expected, which may exceed 1 m (Mauz et al. 2015).

Dating

Accurate dating of beachrocks is a particularly difficult task, although biogenic material, such as shells or corals, can be easily dated with radiocarbon and, if special attention is given to avoid any re-crystallization, reliable results may be achieved (e.g., Mauz et al. 2015). In the case of biogenic material, the age attributed is the time of death of the

organism. After the organism died, it was transported from its in situ position, deposited on a beach, and was later cemented into the beachrock. Although, in many cases, it is possible this sequence to have taken place within a few years, it is likely the time difference between the death of the organism and its incorporation to the beachrock to reach hundreds of years. Therefore, the age attributed by dating an organism can be considered as the maximum age for the lithification of the beachrock (Fig. 7).

A minimum age for this process is possible only by dating the cement. However, several difficulties arise, mainly in the extraction of enough material. In addition, in many cases a beachrock may have undergone multiple diagenetic phases and therefore consist of different cement generations.

During the last decade, many efforts have taken place for dating beachrocks using the method of optically stimulated luminescence (OSL), aiming to reconstruct palaeoshorelines and sea level changes.

According to absolute datings, the beachrocks of the Eastern Mediterranean were mainly formed between 1000 and 5000 years ago (see Voutsoukas et al. 2007, Table 1).

Other Geomorphological SLI

Potholes

Potholes are vertical, circular, and cylindrical erosional features in consolidated rocks, found both in fluvial and coastal

Geomorphology and Sea

Level, Fig. 7 Although biogenic material may be found incorporated into the beachrock, its age should be considered as the maximum age for the lithification

environments. They are developed in zones of breaking rocks, where sand or pebbles act as abrasion tools within depressions, physically excavating the rock (e.g., Taboroši and Kázmér 2013). Their size, diameter, and depth range from a few dm to a few m. Potholes are mostly found at or above sea level, in rock formations frequently scoured by waves; however, they may also develop in deeper water, in areas of rough surf (Taboroši and Kázmér 2013). As they may be formed at various levels in the midlittoral or supralittoral zones as well as in a fluvial environment, they should not be used as sea-level indicators.

Honeycombs and Tafoni

Honeycombs are small cavernous features that may occur in a variety of medium- to coarse-grained rocks, assuming cell-like features, with deep chambers separated by thin walls, which may be produced by several physical processes (Fig. 8). They may form in the spray zone above high tide and although they may indicate the proximity of sea level below them, their accuracy is poor (Pirazzoli 2005). Tafoni are typically cavernous weathering features, which are several cubic meters in volume, and have arch-shaped entrances, concave inner walls, overhanging margins (visors) and fairly smooth, gently sloping, debris-covered floors (Cooke et al. 1993). Their cavernous hollows are believed to largely result from granular disintegration and flaking stimulated by a range of possible processes such as hydration, dissolution, and precipitation of calcareous and saline cements, wetting and drying, rain-wash, and wind deflation (Fig. 9). As they may be found not only in coastal outcrops but also in inland deserts, they should be avoided, alone, as sea-level indicators.

Geomorphology and Sea Level, Fig. 8 Honeycombs may be formed by the sea spray. Although they may indicate the proximity of sea level below them, their accuracy is poor since, depending on the wind conditions, they may form far away from sea level

Sea Caves and Arches

Sea caves are cavities excavated by erosion into cliffs by wave action. They usually occur in the weaker parts of rock formations, following soft layers or unconformable strata, or they may have a karstic origin (Pirazzoli 2005). If their floor is regular and flat, it may be related to a palaeoshoreline indicating a former low tide position (Pirazzoli 2007, Fig. 7) (Fig. 10).

A sea arch is a remnant of a cave opening to the sea on both sides of a headland, beneath a connecting bridge. Both features are commonly inaccurate sea-level indicators.

Algal Rims, Trottoirs

Algal rims may be reef-like structures developing on the outer part of reef flats (mainly *Porolithon*) or on the rocky substrates on coasts subjected to regular wave action (Laborel 2005). In subtropical areas, algal rims (mainly *Neogoniolithon*) may contribute, together with the vermetid *Dendropoma* to the development of trottoirs and even to microreefs growing up to sea level. They are usually easy to date and are considered as excellent sea-level indicators (up to ± 0.1 m accuracy) (Pirazzoli 2007).

Trottoirs are crusts of vermetids or calcareous algae that cover a rocky substratum, forming an almost horizontal line at sea level (Pirazzoli 2007). Trottoirs are also considered as excellent sea-level indicators, especially in microtidal areas, and they are relatively common in the Mediterranean and the tropics (Pirazzoli 2007).

Cornices

On the rocky coasts of the northwestern Mediterranean the calcareous alga *Lithophyllum likenoides* (Philippi) forms a

Geomorphology and Sea

Level, Fig. 9 Tafoni, cavernous weathering features, are not found exclusively in the coastal zone, so they should not be considered as sea-level indicators

**Geomorphology and Sea**

Level, Fig. 10 If the floor of a sea cave is regular and flat, the cave may be related to a palaeoshoreline, indicating a former low tide position

solid cornice (trottoir), the upper level of which is slightly above MSL (Morhange et al. 1982) that may be used as an accurate sea-level indicator. Cornices are bioconstructional features, forming a narrow intertidal reef by *Lithophyllum*, *Dendropoma*, coralline algae, and occasionally also by ostraoids (Pirazzoli 2007).

Summary

Past sea level fluctuations may be studied through various types of indicators, such as geomorphological. A number of geomorphological indicators may allow for past relative sea level reconstructions with variable accuracy. Furthermore,

often there are advantages and disadvantages in the geomorphological feature used to unravel the sea level history of a particular area. The combination of different types of indicators is a powerful tool, not only to verify the results of a particular study but also to improve the accuracy of sea level reconstructions.

Geotextile Applications

Ram K. Mohan¹ and C. G. R. Nair²

¹Blasland, Bouck & Lee, Inc., W. Conshohocken, PA, USA

²Science, Technology and Environment Department, University of Kerala, Thiruvananthapuram, Kerala, India

The technological term “geotextile” has now come to stay in the context of coastal engineering. Perhaps, the original term “filter fabric” is more expressive, but it has fallen into comparative disuse. Geotextiles are really fabric materials used in a “geo,” that is an earth-related, engineering context. These fabrics may be based on natural fibers or man-made synthetic fibers. The latter type of geotextiles are referred to as “geosynthetics.” Geosynthetic materials are generally non-biodegradable, whereas natural geotextiles are often biodegradable. Biodegradability would be an advantage or a disadvantage, depending upon the user needs and use contexts.

Most of the man-made geotextiles (i.e., geosynthetics) are made from polymers of various chemical types. Some common polymers used are polyethylene (PE), polypropylene (PP), polyvinylchloride (PVC), nylons, polystyrene (PS), and polyesters. Natural geotextiles are made from natural fibers, which are also polymers, largely based on cellulose and lignin.

Historical Development

Pioneers of coastal engineering introduced the use of geosynthetics in the 1950s in the United States. According to Bruun (2000), some of the first coastal geotextile research in the United States was carried out at the University of Florida, Gainesville, where plastic filters were tested. Work on the use of nonwoven fabrics for soil reinforcement was done at the Rhone-Poulence textiles in France. Early development work on geotextiles was also conducted in the Netherlands, Britain, Germany, and the United States. Currently, the geotextile industry is quite active in research and development in the United States, through the establishment of the Geosynthetic Research Institute at Drexel University. Additional details on the history of geotextiles can be obtained from Heerten and Kohlhasse (2000).

Material Types and Chemistry

Geotextiles are only a sub-family in the larger family of “Geosynthetics.” Other sub-families include geogrids, geonets, geomembranes, geosynthetic clay liners (GCL), geopipes, and geocomposites. Geotextiles are woven or nonwoven fabrics. Geogrids are plastics formed into open grid-like configuration. Geonets are formed by continuous extrusion of sets of polymeric ribs which when opened give rise to a net-like configuration. Geomembranes are very thin sheets of polymeric materials. GCL’s are thin layers of bentonite clay sandwiched between geotextiles or geonets. Geopipes are simply buried plastic pipes and represent one of the oldest members of the family of geosynthetics. On the other hand, geocomposites are the newest member of the family and are composed of either geotextiles and geonets, or geotextiles and geogrids, or geogrids and geomembranes, etc.

The material used for fabricating geotextiles is invariably some kind of polymer. A “polymer” is a giant molecule of high molecular weight, obtained by polymerizing one or more smaller units called “monomers.” For example, the simple chemical “ethylene” is a monomer. When it is polymerized under suitable conditions, we get “polyethylene” (PE, or polythene). Similarly, the polymerization of simple monomers such as propylene, vinylchloride, or styrene produces PP, PVC, or PS, respectively. In some cases, two monomers are involved in polymerization. Thus, nylons are polyamide polymers formed by the polymerization of diamines and dicarboxylic acids (e.g., hexamethylene diamine and adipic acid). Polyesters such as polyethylene terephthalate (PET) are formed by the polymerization of ethylene glycol and terephthalic acid or derivatives or analogues of these monomers. Polymers commonly used in the geotextile industry include PE, PP, PVC, PET, PS, PA (nylons), and cellulose.

Cellulose is a naturally occurring polymer based on glucose as the monomer.

Another recent development is the use of natural geotextiles, which include fabrics formed using coir, the natural fiber from the husk of coconuts. These geotextiles have exceptional strength due to the high content of a cellulose lignin polymer in them. Besides, they are naturally degradable, which may be attractive in certain applications such as natural stream bank restoration. Other natural fibers include jute, sisal, mixed coir-jute, and mixed sisal-jute.

Geotextile Applications

Barrett (1966), in his well-known and classic paper, discusses the use of fabric materials as reinforcements behind precast concrete seawalls, and under precast erosion control blocks. At present there are several application domains for geotextiles, as discussed below (Heerten and Kohlhasse 2000): (1) filters in erosion control structures (revetments, coastal dikes, etc); (2) separators in the foundation of groins and breakwaters, (3) fabric forms for sand filled bags or tubes as construction elements for groins, dikes, and dunes; (4) flexible scour protection mats at different offshore or coastal structures; (5) reinforcement in dredged material sites; (6) membranes for use in landfill caps; (7) bags for disposing dredged material from navigation channels; and (8) dikes for river training and coastal structures.

Koerner (1998) classifies the applications into six broad categories: (1) *Separation*-is the usage of geotextile to provide physical separation between two material types, while retaining their individual integrity and functions; (2) *Reinforcement*-involves using the geotextile to improve on the inherent strength of the system; (3) *Filtration*-is the use of the geotextile to retain the soil behind it while providing an outlet for dissipation of hydraulic forces; (4) *Drainage*-involves the concept of using the geotextile to provide sufficient fluid movement through it without much loss of the soil behind it; (5) *Containment*-is the concept of providing isolation between two surfaces with the aid of an impervious geotextile; and (6) *Combined uses*-which is the use of the geotextile for any combination of the above listed uses.

Design Considerations

Important general considerations include the following: (1) *Function*-the type of use the geotextile should provide; (2) *Specifications*-the engineering properties that would be needed to satisfy that function; (3) *Availability*-the supply versus demand of that particular type of geotextile in the region; and (4) *Cost*-the price of obtaining and installing the geotextile in place. For small projects with financial

constraints, design by cost and availability is used, which tries to obtain an optimal balance between funds available, area to be covered with geotextile, and unit price of the geotextile.

Key design properties of interest include the following:

- (1) *Physical properties*-includes specific gravity, mass per unit area of the geotextile, thickness, and stiffness;
- (2) *Mechanical properties*-includes compressibility, tensile strength, seam strength, burst strength, and elongation;
- (3) *Hydraulic properties*-includes porosity, percent openings in the geotextile, an equivalent opening size, permeability, and soil retention;
- (4) *Endurance properties*-includes potential for damage during installation, long-term strength loss, abrasion potential, and clogging potential; and
- (5) *Degradation properties*-includes potential for degradation from sunlight, temperature, oxidation, biological action, and hydrolysis.

Various international organizations provide standards for estimating the above properties, with the American Society for Testing and Materials (ASTM 2000) providing the lead. Other leading organizations include the International Standards Organization (ISO), Permanent International Association of Navigation Congresses (PIANC), Geosynthetic Research Institute (GSI) and British Standards Institution (BSI).

Koerner (1998) discusses key aspects of design considerations for the many functional uses of geotextiles, a brief summary of which is presented here

- *Separation design criteria*: Separation function is primal to all geotextiles. Indeed many other functions depend, in their turn, on separation. The use of geotextiles as separators is illustrated by their placement between a soil subgrade (beneath) and a stone base (above). The important criteria here are burst resistance, tensile strength requirements, puncture resistance, and impact resistance.
- *Soil reinforcement design criteria*: Reinforcement of soil is another cardinal application of geotextiles. Seawall reinforcement, reinforcement of embankments, foundation reinforcement and in situ slope reinforcement are the important specific cases. Key properties include tensile strength, puncture resistance, and impact resistance.
- *Filtration design criteria*: Geotextile filters are used behind retention walls, around underdrains, beneath erosion control structures and as silt fences. Adequate fluid permeability and soil retention are the main requisites.
- *Drainage design criteria*: The two main design variations here are gravity drainage design and pressure drainage design. Various manufacturing textiles such as woven silt film, woven nonfilament, nonwoven heatbonded, nonwoven resin-bonded, nonwoven needle-punched, and hybrid systems, are used. Nonwoven needle-punched geotextiles are suited for drainage of fine-grained soil masses such as clays and silt. A high permeability and high soil retention are essential to this application.

- *Containment design criteria*: Application of geotextiles in containment include coastal landfills and other waste barriers. Key properties include low fluid permeability and high soil retention.

Summary

The use of geotextiles in coastal areas has been practiced for a very long time for shore protection needs. However, advances in manufacturing and marketing has led to innovative uses of geotextiles in the coastal zone in recent years. These include the use of sand filled geobags as the core of dunes, sand filled geobag breakwaters and reefs, geobag spur dikes, and deep ocean placement of contaminated sediments in geobags. The future of the geotextile seems limited only by human imagination.

Glaciated Coasts

Daniel F. Belknap
School of Earth and Climate Sciences, University of Maine,
Orono, ME, USA

Definition

Glaciated coasts are dominated or closely affected by glaciers and glacier processes. They include: (1) modern systems in

direct contact with glacial ice; (2) proglacial systems, in front of or adjacent to active glaciers; and (3) paraglacial coasts, formerly glaciated systems that are controlled by glacial geomorphology, sediment sources, and/or isostatic responses.

Introduction
